1.0 EXECUTIVE SUMMARY

In January 1983 the Texas Department of Water Resources contracted with Lockwood, Andrews, & Newnam, Inc. in association with Environmental Science and Engineering, Inc. and Harding Lawson Associates to conduct a remedial site investigation at the French Limited abandoned hazardous waste site. The 22.5-acre site is located in Northeast Harris County, approximately 2 miles from Crosby, Texas. It is triangular in shape bordered on the northwest by U.S. Highway 90 and on the south by Gulf Pump Road. The Riverdale Subdivision lies immediately to the southwest and has an active population of approximately 100 people. East of Riverdale and immediately south of the site, Harris County operated a sanitary landfill in the 1960's on an 18.5-acre site. A portion of the landfill site is currently used on an intermittent basis as a pipe storage yard. The remaining areas surrounding the site are largely undeveloped with numerous abandoned sand pits and low-lying swampy areas. Some commercial timber operations and mineral exploration have been conducted in the past immediately north of the site. Indiscriminate dumping of household garbage and commercial refuse is prevalent along area roads and ditches. The area plays host to sport fisherman as well as water sport enthusiasts on the nearby lakes and ponds and the San Jacinto River.

Operations at the French Limited site were conducted between 1966 and 1972 during which time approximately 2.5 million cubic feet of industrial wastes were received. The majority of this waste was deposited in an unlined pit, formerly an active sand pit; however, some wastes were stored upon arrival in several large tanks and burned in an open pit process. The disposal site was operated under a temporary permit issued by the Texas Water Quality Board. This permit was revoked and French Limited was ordered to cease operations in 1973 after extensive public hearings and legal proceedings. As part of the settlement, French Limited was ordered to remove all of the site structures, tankage, and process equipment. The site was deeded to the state as a part of the settlement.

The 100-year floodplain of the San Jacinto River encompasses the entire site, and the river has completely inundated it at least four times in the recent past. During one of these flood events, the dike surrounding the waste pit was

overtopped and breached, and contaminated sludges were discharged into an adjacent slough. An emergency action repaired the dike and pumped the majority of the discharged sludges back into the pit. The floating portion of these sludges was removed and disposed of during a later planned removal.

A broad sandy deposit, approximately 40 to 50 feet thick, underlies the site and forms a shallow aquifer upon which many of the local inhabitants rely for drinking water. Ground water in the shallow aquifer has been heavily contaminated in the areas immediately surrounding the waste pit by leaching action of the sludges. The ground water in the areas around the contaminated slough and south of the main waste pit indicate a much lower level of contamination. Residents of the nearby Riverdale community have in the past complained of organic odors, oily sheens, and bad taste in the drinking water from shallow wells.

Dewatering operations at surrounding sand pits has resulted in numerous shifts in area groundwater gradients with the subsequent spread of contaminants. At this time, significant groundwater contamination appears to be moving from the main waste pit to the south. Contaminants in the shallow ground water include:

- · Volatile organic compounds
 - Benzene
 - Numerous chlorinated hydrocarbons
- Base/neutral organic compounds
 - Naphthalene
 - Other polynuclear aromatics
- Phenols
- · Heavy Metals
 - Chromium
 - Copper
 - Lead
 - Zinc

Underlying the shallow aquifer, separated by approximately 70 feet of a hard, highly plastic clay, is a 30-foot thick sand stratum. Ground waters in this aquifer appear to have no contamination.

7

Underlying the two aquifers previously discussed and separated by several hundred feet of clay are the Chicot and Evangeline aquifers, the primary drinking water source for metropolitan Houston. These aquifers appear to be in little danger of immediate contamination, however should they become contaminated a large number of people could potentially be affected.

The surface of the site can be separated into distinct geographical areas, based upon land use or topography:

- · The main waste pit;
- The slough immediately north and west of the pit;
- The slough and drainageways north of U.S. Highway 90;
- The Riverdale Subdivision;
- The Old Harris County Landfill; and
- The abandoned sand pit and drainageway south of the site.

- A9.9

The main waste pit covers an area approximately 8 acres in size and has an average depth of approximately 10.6 feet. The pit contains approximately 48,000 cubic yards of sludges and contaminated sediments and approximately 24.5 million gallons of contaminated water. The sludges are composed of a wide variety of organics including the following:

- · Volatile organic compounds
 - Benzene and benzene derivatives
 - Numerous chlorinated hydrocarbons
- Base/neutral organic compounds
 - Naphthalene
 - Other polynuclear hydrocarbons
- PCBs (at greater than 50 ppm levels)
- Metals
 - Zinc
 - Chromium

The water quality in the pit appears to vary with the season; however, the contamination in the water is of the same nature as that in the sludges, except at a much lower level (ppb versus ppm). Contamination in the pit water was generally restricted to the lower layers (from bottom to approximately mid-depth).

24.5×106= 750011 Ft ate

The slough north of the main waste pit runs along the south side of U.S. Highway 90 from about the mid-point of the waste pit to a point approximately 700 feet from the westernmost portion of the pit. It is approximately 100 feet wide at its widest point but is generally 50 feet wide with depths ranging from 4 to 6 feet. The slough received the majority of wastes from the main pit when the dike was breached. Sediments in the slough exhibit the full range of contaminants found in the main pit sludges, but at much lower concentrations. Soils along the banks of the slough are littered with patches of dried and semi-dried sludges of similar composition and contaminant levels as those found in the pit. Surface waters do not appear to be affected, except for trace concentrations of metals (primarily chromium, copper, and zinc).

The slough north of U.S. Highway 90 is hydraulically connected to the slough north of the main waste pit during high water. This slough includes the "fishing hole" beneath the U.S. Highway 90 bridge immediately north of the main waste pit. From the "fishing hole" the slough runs in a westerly direction along the north side of the highway for a distance of approximately 1,500 feet. It is generally 30 feet wide with depths ranging from 4 to 10 feet. The slough is drained by a broad swampy drainageway extending from the northwest corner of the fishing hole north and west towards the San Jacinto River. Sediments in the slough exhibited trace concentrations of several base/neutral compounds and PCBs. The higher levels of contamination were seen in the sediments taken from locations hydraulically closer to the main waste pit. Surface waters were free of organic contamination but had low level concentrations of several metals. Fish tissue from specimens taken in the fishing hole indicated a low level bioaccumulation of PCBs and some metals.

Sediment samples taken in the drainageway draining the slough exhibited trace concentrations of PCBs and several base/neutrals similar to those found in the main waste pit sludges. A soil sample taken from the dry bank of the drainageway indicated trace concentrations of PCBs and two phthalate compounds.

The Riverdale Subdivision lies immediately southwest of the site across Gulf Pump Road. During flood events water flowing down the slough from the site discharges into the subdivision. Pond sediments and soils from dry drainage ditches indicated trace concentrations of PCBs and several phthalates. Fish tissue from speciments taken on a pond in the subdivision indicated a low level bioaccumulation of PCBs and some metals. The primary concern in Riverdale is the shallow ground water upon which most of the residents rely for drinking water. Groundwater samples from two residences and one monitoring well located in the subdivision indicated no organic contaministion at the time of sampling.

Adjacent to the Riverdale Subdivision to the east is a closed Harris County sanitary landfill. The landfill appears to be leaking leachate into the ground water south and downgradient of the French Limited site. At this time the ground water beneath the landfill is downgradient of both the site and the Riverdale Subdivision.

Directly south approximately 300 feet from the French Limited site and adjacent to the old landfill is an abandoned sand pit. This pit drains into a marshy area connected to a well-defined drainageway approximately 300 feet to the south. The drainageway flows to the south and west approximately one mile to another small body of water, Rickett Lake. This entire area is on the flow path of flood waters moving across the French Limited site. Sediment samples taken from the lake immediately south of the site indicated trace concentrations of one volatile aromatic and several base/neutral organic compounds similar to those found in the main waste pit sludges. Surface water in the abandoned sand pit showed no organic contamination, however trace concentrations of several metals were found. Fish tissue from specimens taken from the lake indicated a low level bioaccumulation of PCBs and some metals. Sediments samples taken at key points along the drainageway and in Rickett Lake indicated trace concentrations of PCBs and several phthalate compounds.

The population most likely to be affected by this contamination includes:

- · Residents in the nearby Riverdale Subdivision;
- Sport fishermen that frequent the fishing hole under U.S. Highway 90,
 and sloughs and some of the abandoned sand pits in the area; and
- Harris County Precinct 2 maintenance personnel

The pathways by which these people may become exposed to the contamination are:

- Consumption of contaminated ground water;
- Ingestion of contaminated aquatic species and plants; and
- Direct contact with contaminated soils and surface water.

Volet les air Of the pathways, the first is probably the most significant. Unlike the last two, groundwater contamination has the potential to increase and spread outward unhindered with time. This movement will occur as long as a sufficient concentration of the contaminant mass remains within the French Limited site, and could eventually (as it has in the past) result in contamination of the drinking water supply for local residents.

2.0 INTRODUCTION

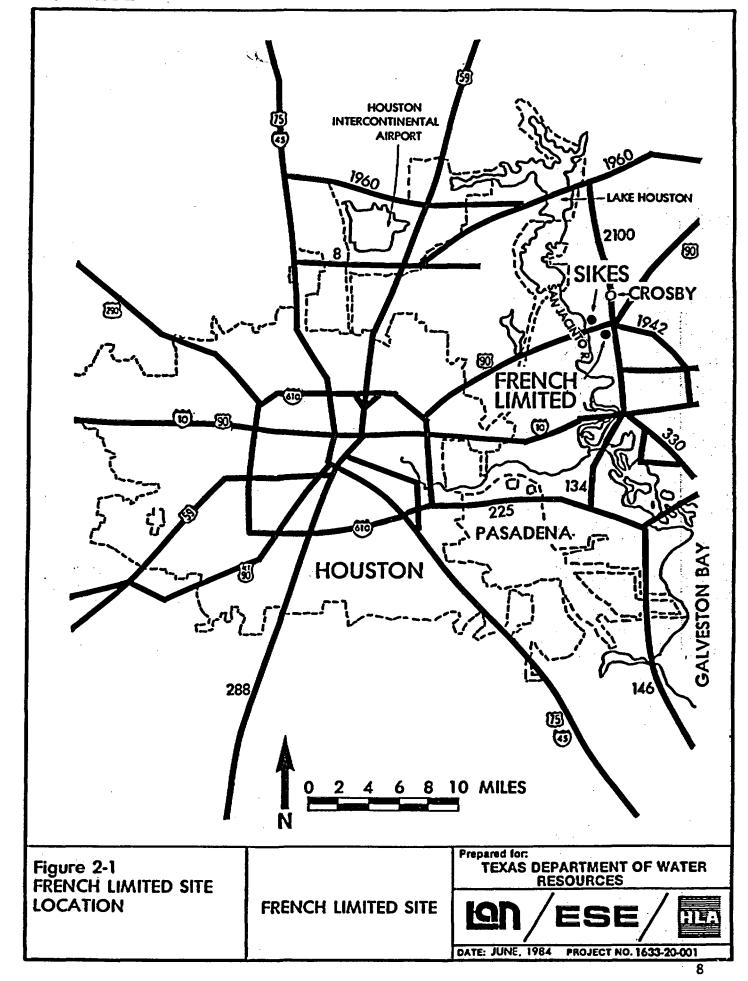

2.1 LOCATION

The French Limited site consists of an abandoned waste impoundment located on a 22.5-acre tract approximately two miles southwest of Crosby, Texas. The site is in Harris County, 20 miles east-northeast of Houston in the floodplain of the San Jacinto River (see Figure 2-1). The French Limited site is about JIN DE FRENTIZE SUMPERTO 16 miles northwest of Galveston Bay.

2.2 SITE HISTORY

The site received about 100,000 barrels of industrial waste per year for six years between 1966 and 1972. The majority of this waste was disposed of in an unlined pit approximately 8 acres in size. Water in the pit had a pH of 2.3 on February 1, 1971, and contained 550 parts per million (ppm) iron (dissolved), 1,400 ppm chlorides, and over 8,000 ppm total dissolved solids. Three monitor wells installed by French Limited near the pit (reported to be 17 to 28 feet deep) contained total dissolved solids ranging from 1,060 to 2,150 ppm. locations of these wells are unknown. Residential wells in and around the Riverdale Subdivision contained total dissolved solids ranging from 87 to 381 ppm (Public Hearing Record, February 22, 1971). Prior to this Public Hearing, area residents had complained for some time about tastes and odors in their well water. Many residents were hauling in drinking and domestic water supplies. The property was deeded to the State of Texas following extensive litigations and French Limited's final bankruptcy in 1973.

The site has been flooded by the San Jacinto River in 1969, 1973, 1979, and May 1983. The flood of 1973 flushed some contaminated water out of the pit without any complaints of damage to the downstream ecology. The flood of April 1979, caused a breach in the northern dike of the pit, providing an avenue for the discharge of contaminated sludges into the adjacent swamp north of the pit. The May 1983 flood occurred after the sampling for the investigation described in this report was performed. The berms around the main waste pit were inundated with approximately 2 feet of water. A previously-installed oil boom, fencing and vegetation along the berm helped to contain the floating oily residues, and very little appeared to have escaped the main pit area.

Preliminary remedial actions have been taken since the 1979 flood to repair the dike which was breached and to prevent further discharge of contaminants. A limited effort was completed in 1982 to collect and remove scum and floating oily residues from the swampy area north of the dike. A portion of these floating oily residues was left contained behind a floating boom at the west end of the main pit. Following the flood of May 1983, these floating oily residues behind the boom were removed from the site by the USEPA to reduce risks during future floods.

Sampling and inspection of the French Limited main pit in June 1976 revealed that water was at a pH of about 7.5, and TOC averaged about 116 ppm. Sludges in the water of the pit exceeded 2 feet in depth, and contained 1,066 ppm total organic carbon (TOC) and 10,464 ppm zinc (TDWR Memorandum, July 9, 1976). The Harris County Pollution Control Board collected data in 1979 which indicated that the water quality in shallow residential wells near the site had improved considerably since 1971 (TDWR Memorandum, December 11, 1979)

In December 1982, the Texas Department of Water Resources contracted with the LAN/ESE/HLA team to perform a remedial investigation and feasibility study of the French Limited site.

2.3 ENVIRONMENTAL SETTING OVERVIEW

The site lies about 10 feet above mean sea level and is about one mile east of doesn't the San Jacinto River. The surface drainage is southwest to the San Jacinto live with River. The soils are made up of sands to a depth of approximately 65 feet and commany clays from 65 to 125 feet. A deep aquifer exists in a confined sand stratum pg. 2 below a depth of 125 feet. The Upper Water-Bearing Zone beneath the site resides near surface in the shallow sands. The prevailing water surface in the disposal pit appears to conform to the water table in this Upper Water-Bearing Zone.

Forest canopy vegetation of this area consists of loblolly pine, slash pine, water oak, willow oak, elm, green ash, cottonwood, sweetgum, and in the wetter areas bald cypress. The dominant plant on site is sesban, a leguminous shrub which is common in disturbed wet areas of the region.

Deer and small mammals, such as cottontail rabbit, skunk, fox, raccoon and opossum are common. Harris County is a wintering place for geese, ducks, egrets, herons, rails, coots, gallinules, and other migratory birds.

Land use in the county is divided between cropland, pasture, and range (40 percent); forest (15 percent), with most of the remaining area being urban. Rice, grain sorghum, corn, cotton, beef cattle, and timber are the principal agricultural products, and oil refining is the chief industry. Harris County is also one of the nation's leading producer of chemicals, fertilizers, and insecticides. Galveston Bay supports commercial fishing and shellfish harvesting.

2.4 OBJECTIVES

The work program for the French Limited site was structured into two phases: investigation of site conditions (Phase I); and, if appropriate, evaluation of engineering feasibility of site control measures (Phase II). The purpose and objectives of the site investigation were to characterize the site in terms of:

- 1. waste materials present,
- 2. magnitude and extent of contamination,
- 3. rate and direction of waste migration,
- 4. target receptors, and
- 5. site geology and hydrology.

The objective of the feasibility study are to develop and evaluate alternative remedial measures considering technical feasibility, economic factors, environmental impacts, regulatory constraints and timeliness of completion.

This report discusses the investigation of site conditions conducted during Phase I. Two field sampling and analysis periods are covered by this report. The first intensive field investigation occurred in April 1983, when ground and surface waters as well as sludges, sediments, soils, and fish tissue were studied. This sampling was supplemented by further detailed sampling in November 1983. Air monitoring with an HNU photoionization detector at the beginning of Phase I indicated very low to undetectable levels of volatile gases in the air around the French Limited site. On this basis, further air monitoring studies were not utilized to characterize the site.

all with sometime of the

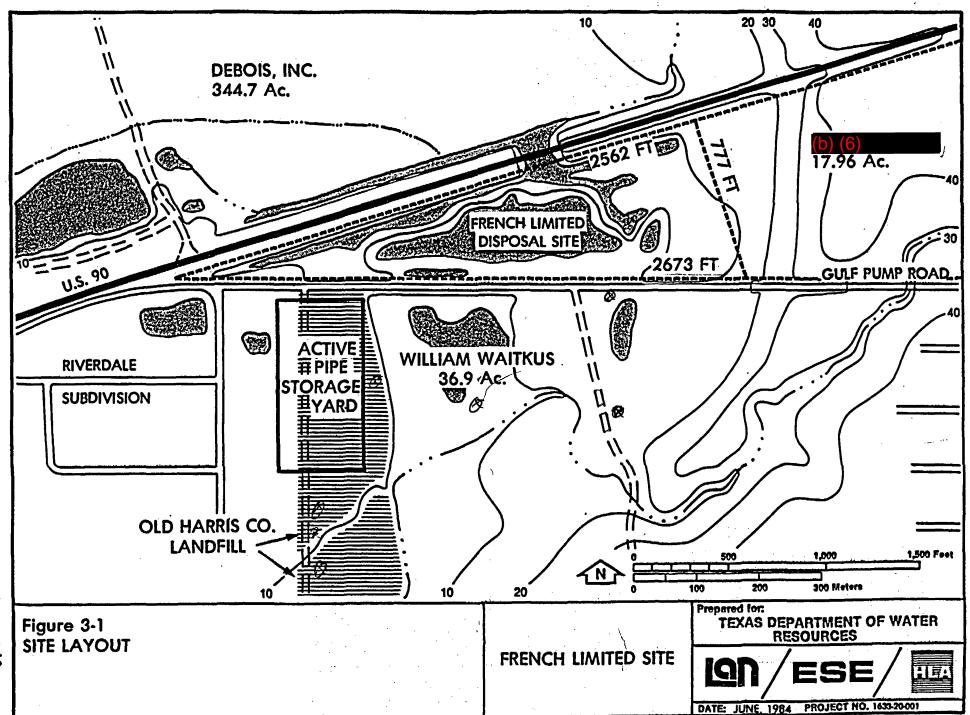

3.0 ENVIRONMENTAL SETTING

3.1 SITE LAYOUT

The French Limited site is located immediately east of the intersection of U.S. Highway 90 and Gulf Pump Road, southwest of Crosby, Texas and east of Barrett, Texas. The triangular site comprises 22.481 acres out of the Humphrey Jackson Labor Survey, Abstract 37 (see Figure 3-1). It is bordered on the south by Gulf Pump Road, on the northwest by U.S. Highway 90, and on the east by a 17.96-acre tract owned by (b) (6)

The predominant feature on the site is an approximately 8-acre pit completely surrounded by an earthen dike. A small pit lies east of the main pit, and sloughs and swampy areas are located west, north, and east surrounding the pit. The most prominent of the smaller pits is the one due east of the site and the borrow pit north of the site under U.S. Highway 90. Two entrances off Gulf Pump Road provide access to a dirt road which rings approximately three-quarters of the main pit. Access to the north side of the main pit is by means of this road.

The area immediately surrounding the site is largely undeveloped with numerous abandoned sand pits and large swampy areas. The Riverdale Subdivision lies to the southwest of the site across Gulf Pump Road. The subdivision consists of acreage lots with residential housing. Adjacent to the Riverdale Subdivision to the east is a pipe storage yard located on an unimproved 36.919-acre tract out of the Reuben White Survey, Abstract 84 and owned by William Waitkus. Adjacent to the pipe storage yard due south of the main waste pit is a pit or pond approximately 3 acres in size. The remaining tracts of land south of Gulf Pump Road are undeveloped with brushy vegetation, and intermittent swampy areas predominate. The east side of the site is largely dense woods with intermittent swampy areas, garbage dumps, and some abandoned sand pits. North of the site, across U.S. Highway 90 the property is undeveloped, densely wooded, and swampy. This tract of land, 344.71 acres out of the Humphrey Jackson Labor Survey, Abstract 37 is owned by Debois, Inc. with (b) (6)

An aerial photograph of the French Limited site vicinity is shown in Appendix A. A boundary and topographic map is also included in Appendix A.

3.2 TOPOGRAPHY

The topography of the site and the surrounding area was analyzed using aerial photographs, USGS topographic maps and the Environmental Geologic Atlas of the Texas Coastal Zone--"Galveston-Houston Area," issued by the Texas Eureau of Economic Geology. This analysis was supplemented by ground reconnaissance.

The area surrounding the site contains three distinct natural topographic zones, each having different geological conditions and supporting a slightly different environmental and biological assemblage (see Figure 3-2). The three zones are simply a manifestation of the natural ground surface elevation and its relationship to the fluvial system of the nearby San Jacinto River.

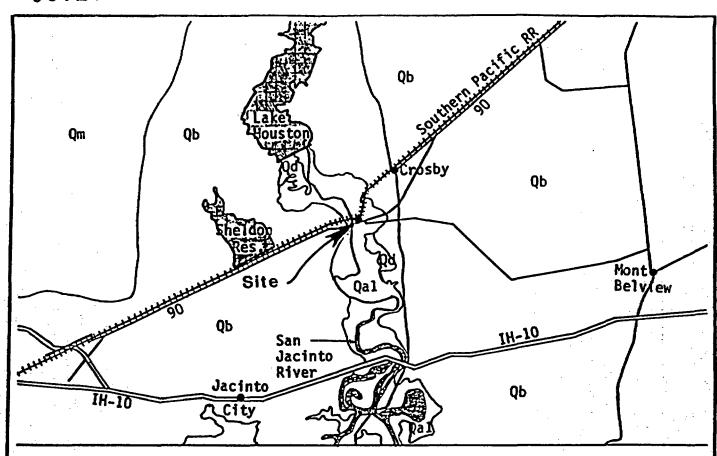

The natural zones have been significantly influenced by man-made features and structures. Dominant man-made topographic features such as roadbeds, drainage ditches, sand quarry pits, and indiscriminant dumping have changed the natural ground surface and altered the natural hydrological and biological conditions in the vicinity of the site.

Zones Should be Shown on the site.

Zone I—Zone I consists of the river floodplain that extends from the San Jacinto River to approximately 800 feet east of the main waste pit. The natural ground surface in the area varies from a high of approximately Elevation 25 feet msl (Elevations refer to Mean Sea Level Datum, 1963 Survey) in Riverdale subdivision to a low in the site area of approximately Elevation 10 feet. This zone has developed through deposition from natural flooding and overbanking of the river. Drainage is generally poor, and the area is flood prone.

At the time of the aerial survey (March 1983), the water surface in the slough north of the main waste pit was at Elevation 9.7 feet, and the water surface in the main pit was at Elevation 10.6 feet.

Man-made features at the site are the most distinguishing topographic features of this zone. The main pit, with a water surface elevation of 10.6 feet, is

EXPLANATION

Qal Alluvium

Clay, silt, and sand, organic matter abundant locally; includes point bar, natural leves, stream channel, backeneamy, seastal march, mud flat, and narrow beach deposits, the last shown by line symbol

Qd Deweyville Formation

Band, silt, and clay, some gravel; includes point bar, natural leves, stream channel, and backcowamp deposits at a level only nightly above that of the present flood plain; cand courser than in alluvium; surface characterized by relict meanders of much larger radius of surveiture than those of present streams, some scallered pimple mounds; thickness locally more than 50 feet, fligh level Deveyvillo surfaces cut in the Beaumont Fermation and high level Deveyville deposite along Trinity Ror are intermediate in position between the Beaumont surface and the level of most Deveyville deposite

Qb Beaumont Formation

Beaument Permation, Qb, with barrier island and beach deposits, Qbb, mapped separately. Beaument Permation, Qb, mostly slay, sitt, and sand; includes mainly stream channel, point bar, natural leves, and backersamp deposits and to a lesser extent seastal warsh and mud fat deposits; concretions of calcium carbonate, from oxide, and from-manganess exides in some of weathering; ourface almost featureless, characterized by relict river channels shown by meander patterns and pinula mounds on mandersbelt ridges, uspearated by areas of low, relatively emouth, featureless backeroamp deposits without pinule mounds; thickness 100± feet. Barrier island and beach deposits, then that of surrounding deposits, characterized by numerous yimple mounds and rounded degressions; probably part of "Inglesides" barrier island system; thickness less than 30 feet. Prairie Formation is a more recent name for deposits in Louisiana equivalent to Beaument Formation in Texas)

QM Montgomery Formation

Clay, oilt, sand, and very miner siliceous gravel of granule and small pubble size, gravel more abundant northwestward, locally calcareous, concretions of calcium carbonate, iron exide, and iron-mangeness exides common in zone of weathering; fluviatile; surface fairly flat and featureless except for numerous rounded shallow depressions and pimple mounds; thickness 100 ± feet. (Upper part of Liesie Formation as proviously mapped)

Figure 3-2 REGIONAL GEOLOGIC MAP

FRENCH LIMITED SITE

Prepared for: TEXAS DEPARTMENT OF WATER RESOURCES

DATE: JUNE, 1984 PROJECT NO. 1633-20-002

enclosed by a dike ranging in elevation from 13.9 to 17.4 feet. North of the pit, the road bed of U.S. Highway 90 ranges from Elevation 25.4 to 26.8 feet. South of the main pit is Gulf Pump Road which ranges from Elevation 12.3 to 17.2 feet. East of the site, Gulf Pump Road rises to an elevation of nearly 40 feet.

Another man-made topographic feature is the indiscriminant refuse dump along both sides of Gulf Pump Road southeast of the main pit that ranges in Elevation from 9.7 to 18.6 feet.

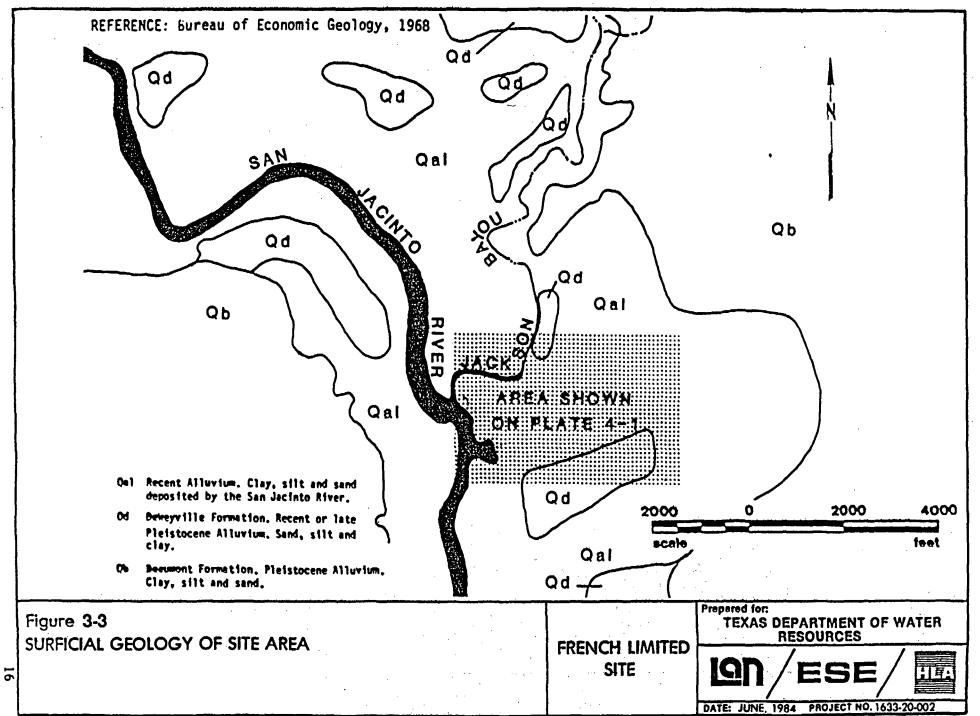

Zone II-A transition zone occurs from the edge of the floodplain to the higher grasslands just west of the City of Barrett. This transition zone is slightly sloped, rising from Elevation 10 feet to approximately Elevation 45 feet over a 1,000-foot distance. This zone is heavily wooded with mixed pine and hardwood. Although some of this zone contains marsh-like conditions typical of Zone I, it is mostly well-drained and slightly sloped. Surface soils consist of clay and sand.

Zone III—From just west of Barrett to the Cedar Bayou Basin to the east, the area is generally flat prairie uplands with elevations ranging from 45 to 55 feet. These are mostly cultivated lands. Uncultivated areas are overgrown by natural occurrences of native grasses, cactus, mesquite, huisache, and hackberry. Geologically this zone is classified as interdistributary clays with belts of distributary and fluvial sands and silts.

3.3 GEOLOGY

3.3.1 Regional Geology

The French Limited site is in the Coastal Plain Region, which consists of sedimentary materials deposited by formerly and presently active geologic processes in deltaic, alluvial, eolian dune, bay-estuarine, and barrier-island-shoreline systems (see Figure 3-3). The Southeast Texas portion of the Coastal Plain is underlain by a thick mass of sediments (in excess of 30,000 feet) that are now slightly inclined downward toward the Gulf; upper sections have been considerably eroded. Successively older geologic formations crop out progressively farther inland from the coast line.

The deposits of the Southeast Texas Coastal Plain belong chiefly to the Tertiary Period (70 million to 3 million years old), to the Pleistocene (3 million to 0.2 million years old) and to the Holocene (0.2 million years old to present) epochs. Holocene deposits in the site area consists of river alluvium. The Holocene deposits are underlain by the differentiated formations (Beaumont, Montgomery, Bentley and Willis) of the Pleistocene epoch, which forms a very smooth, gently seaward tilted plain. The near surface formation is the Beaumont consisting of clays with interbedded silts and sands which have been deposited by river deltas and floodplains. Subsequent to their deposition, the soils were desiccated when the sea levels were much lower than they are now. Consequently, the soils are overconsolidated, generally have high strengths and typically have a blocky secondary structure with some slickensides.

The low relief that characterizes the Coastal Plain is occasionally disrupted by entrenched streams. These include cut channels across the plain that are actively growing through headward erosion.

The Houston area is located in a Seismic Zone O according to the Uniform Building Code. The primary geologic hazards in the area are subsidence caused by deep groundwater withdrawal and related ground faulting. Ground faults in the Houston area are generally inclined 60 to 75 degrees from the horizontal, extend downward for thousands of feet, and are roughly parallel to the coast. Based upon a review of available data sources, no known faults pass through the site area.

Maximum subsidence in the Houston area has exceeded 8 feet over the last 75 years. Based on elevation corrections of USGS Bench Mark D690, approximately 4,000 feet west of the site, the site subsided 0.93 feet between 1963 and 1973 and 0.32 feet between 1973 and 1978.

Elevations presented in this text are based on the 1963 datum. For a rough approximation of the 1983 elevations, subtract 1.5 feet from the 1963 elevation.

3.3.2 Local Geology

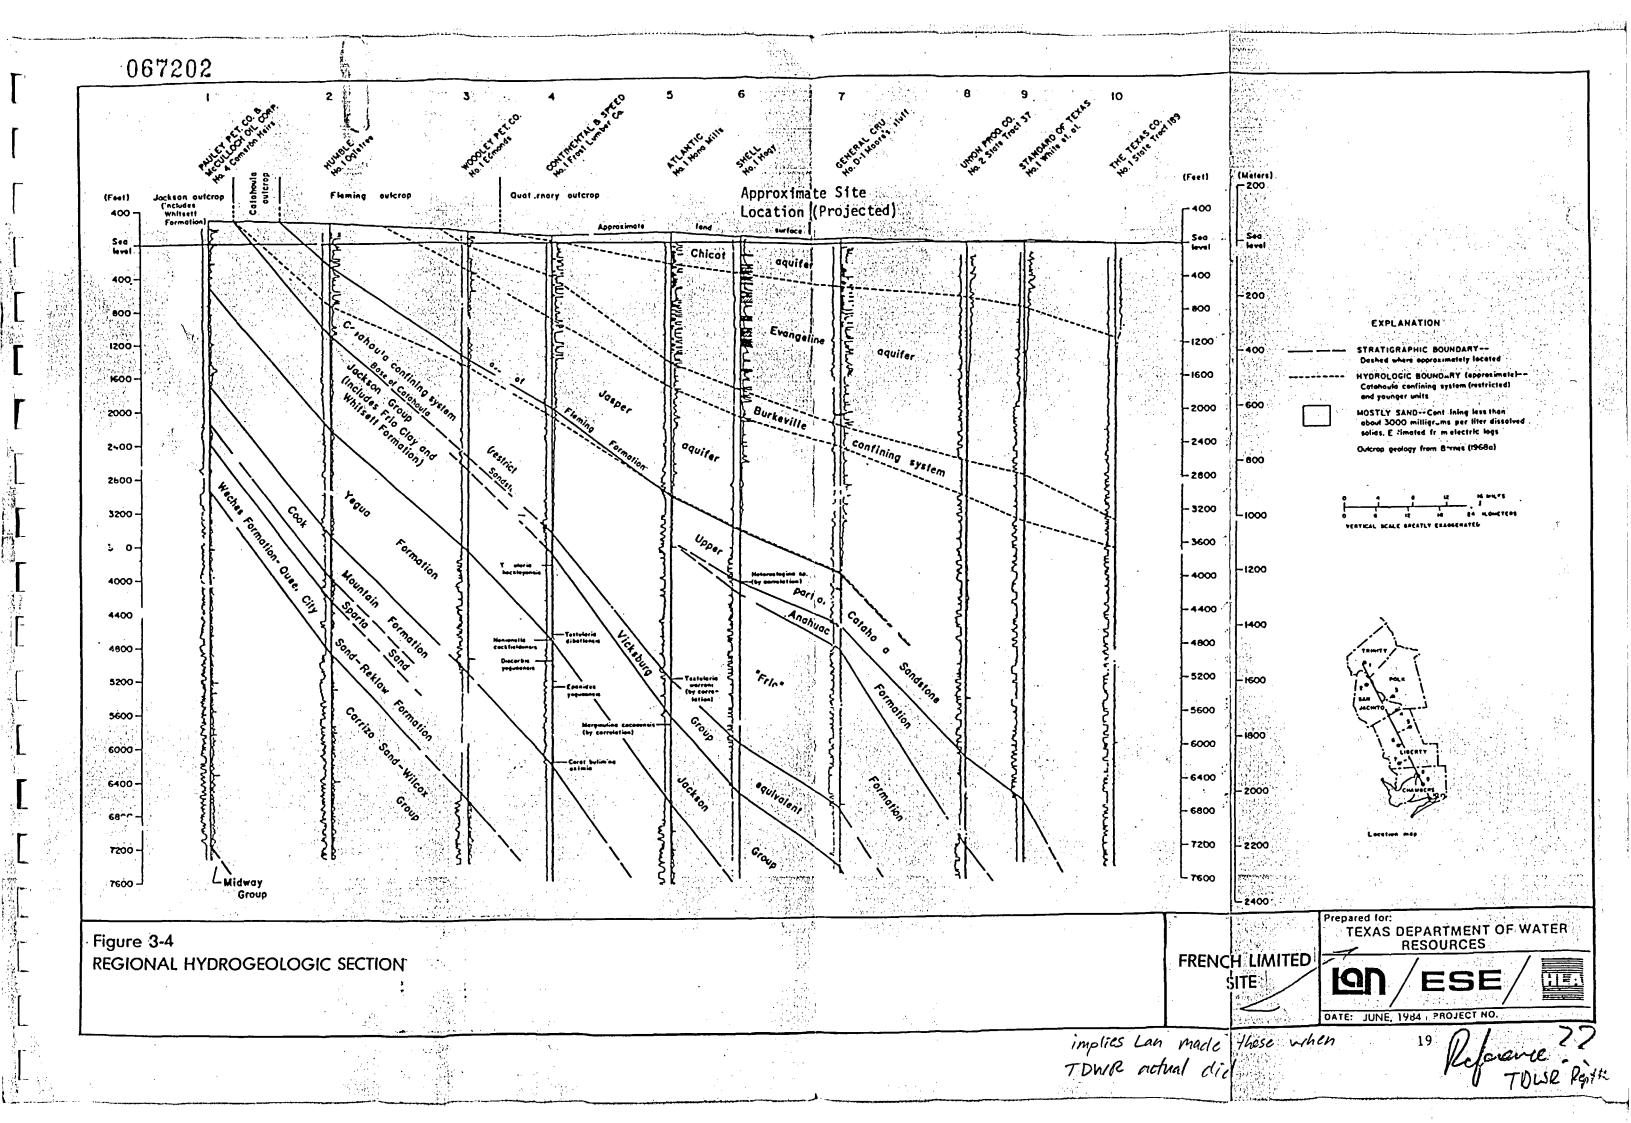

The French Limited site is in the San Jacinto alluvial valley on the east side of the river. There are remnants of Early Hologene alluvial deposits (Deweyville Formation) at the surface (Figure 3-4) and beneath the site area. Most of the surficial deposits in the site, however, are later Holocene (Recent) alluvium. The alluvium has been deposited in a channel incised in the Pleistocene Beaumont Formation.

As the river meander gradually moves across the valley, it erodes older deposits on the outside of the bend and deposits predominantly sandy material on the inside of the bend (point bar deposits). Eventually, the meander doubles back on itself and the river takes a direct path, cutting off the meander which then becomes an oxbow lake. During times of flood, the lake fills with finer material (silt and clay). As the river continues to meander back and forth across the valley, the older deposits are periodically cut into and new alluvium is deposited adjacent to the old. This process has resulted in the alluvial deposits encountered at the French Limited site. Accordingly, by the nature of their deposition, the grain size of the deposits varies laterally and vertically across the site.

The river meander eroded the Beaumont Formation to depths of 20 to 55 feet in the site area. The alluvial deposits in this upper stratum are predominantly sands; however, silt and clay layers are also present.

The Holocene alluvial deposits are underlain by the Beaumont Formation which consists predominantly of clay with some discontinuous silt and sand lenses generally less than a few feet thick. At a depth of approximately 125 feet (Elevation -110), a sand stratum is present that extends to the maximum depth explored during this investigation (155 feet).

The limits of the river meander extend approximately 800 feet east of the main pit beyond which the Beaumont Formation is present at the ground surface.

3.4 HYDROGEOLOGY

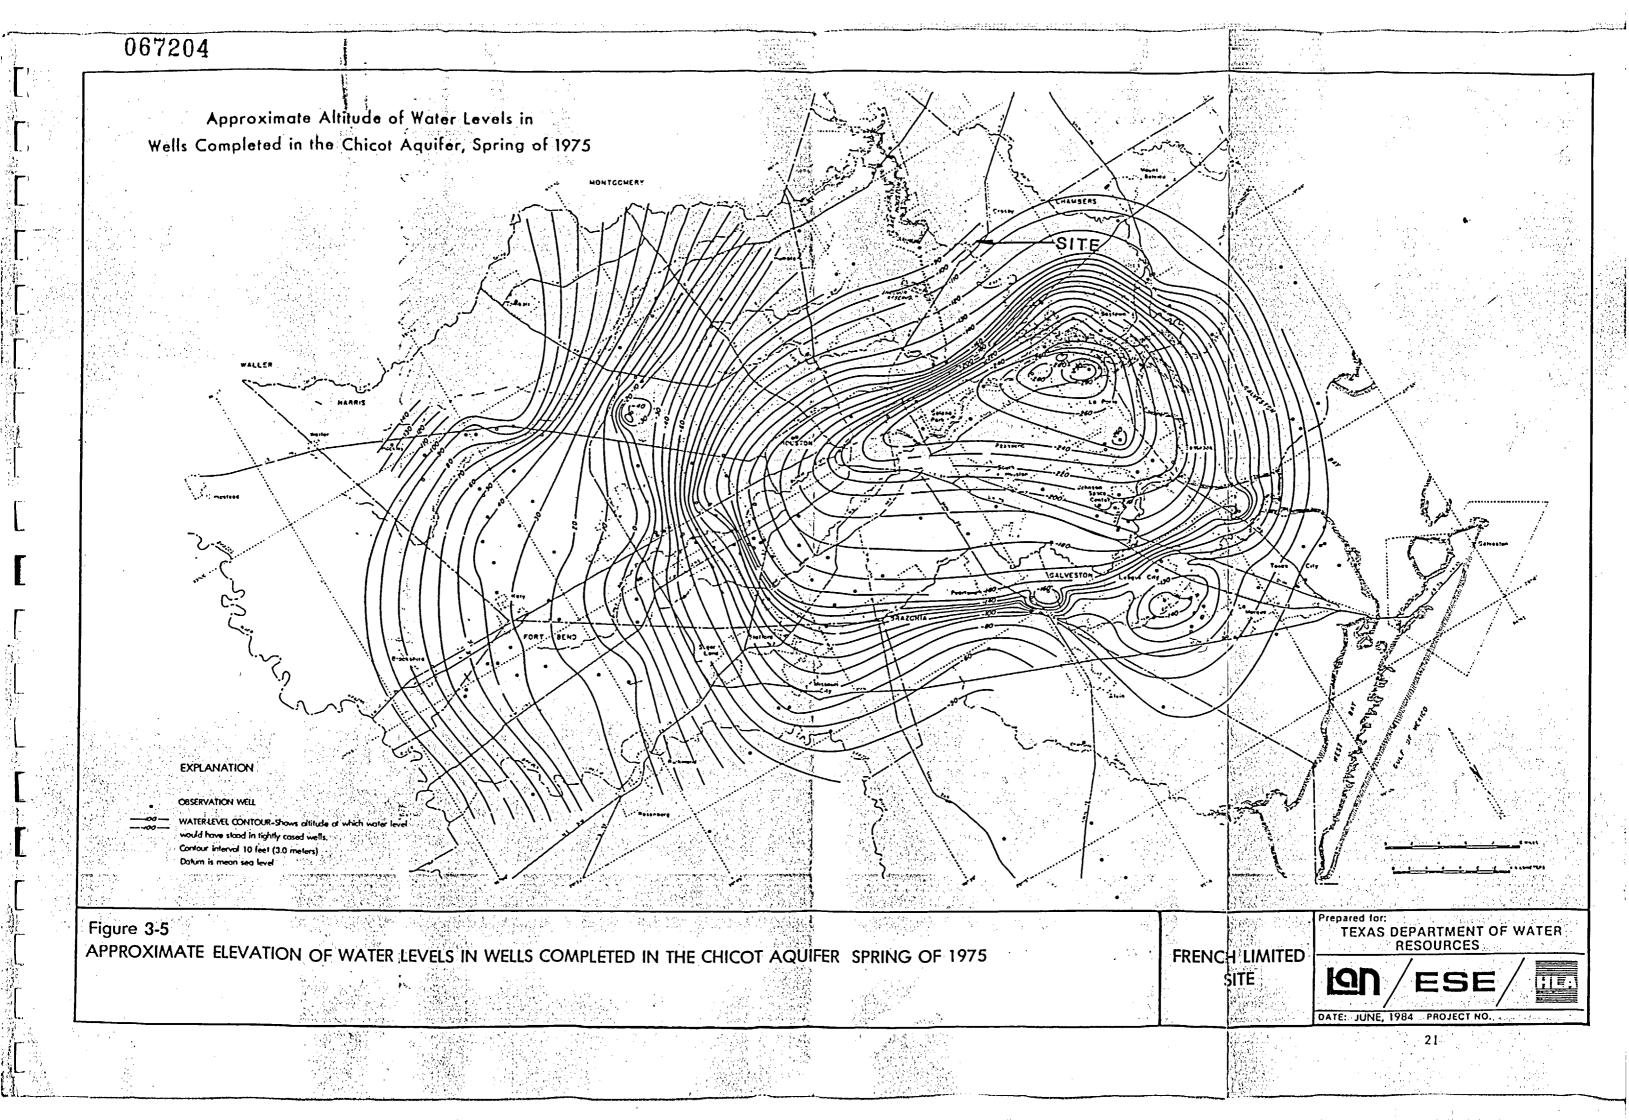

3.4.1 Regional Hydrogeology

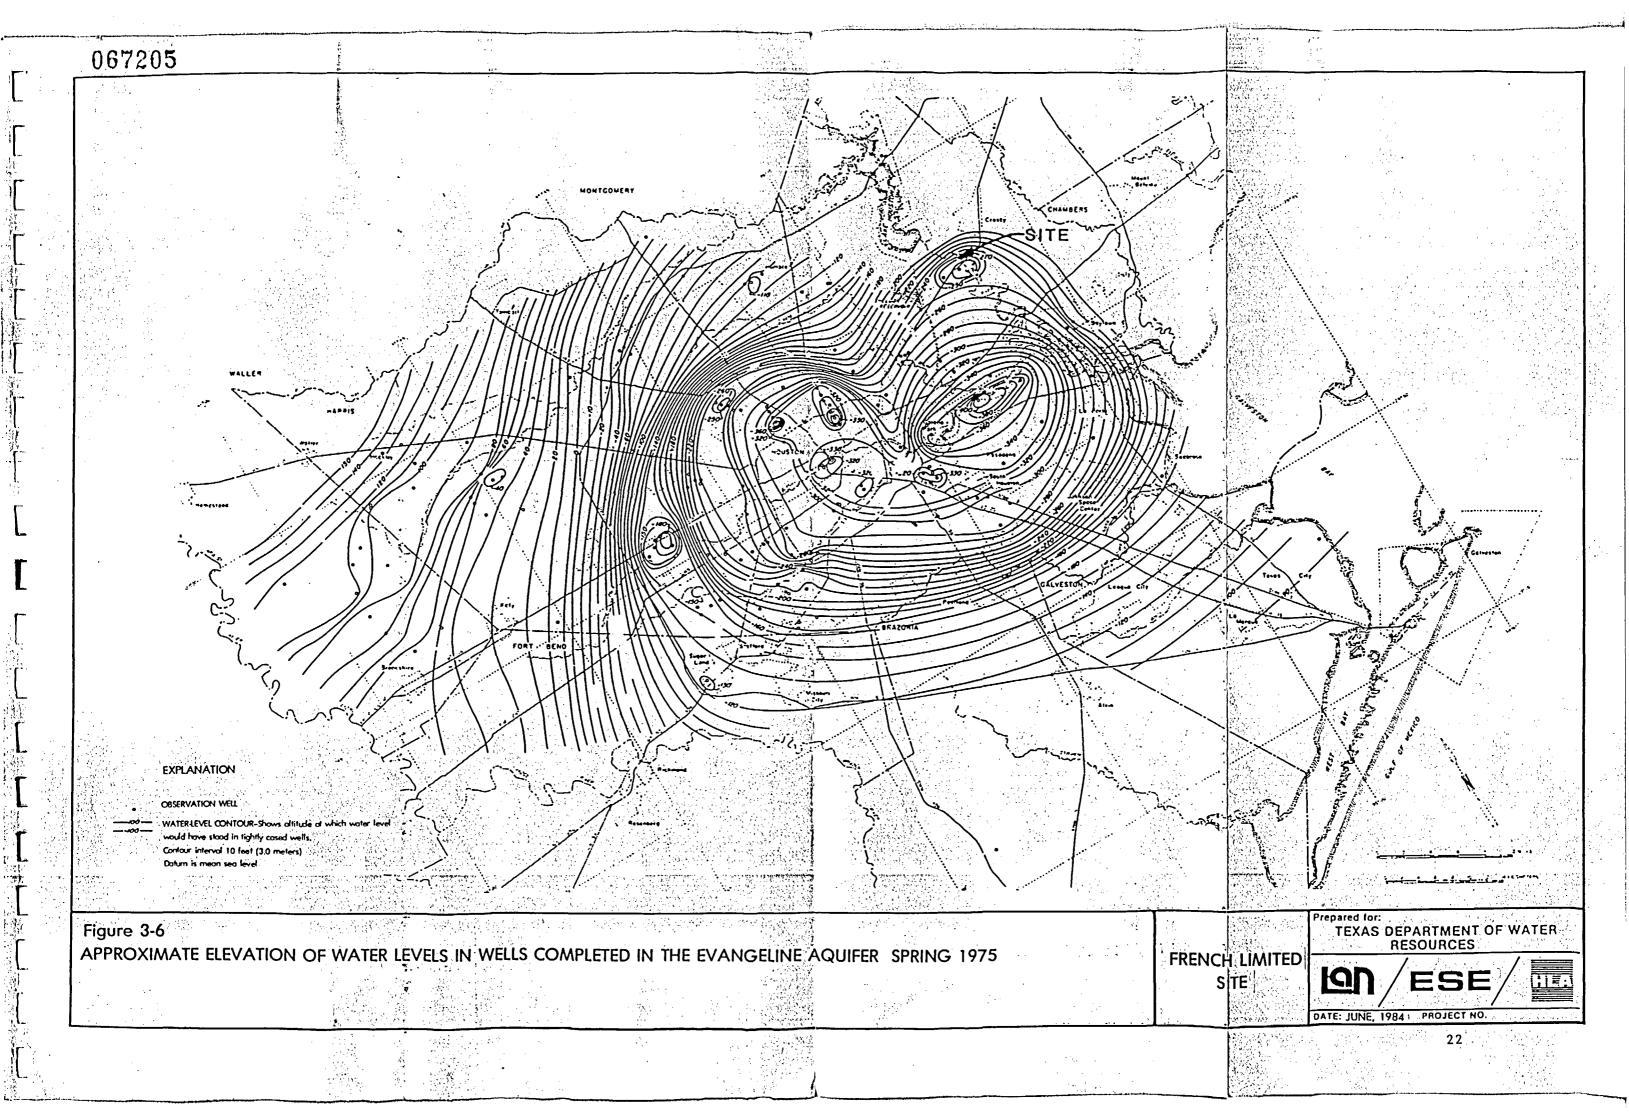

Groundwater in the Coastal Plain Region occurs under both confined and unconfined conditions. Shallow aquifers in alluvial valleys are important sources of groundwater for limited rural domestic and livestock watering purposes. Wells in these aquifers are generally less than 50 feet deep, and typically yield a few gallons per minute. Although most of these small alluvial aquifers are unconfined, near-surface impermeable material may create localized confined conditions. Recharge of the unconfined aquifers is mainly from local infiltration of rainfall, rumoff, and ponded water. Deeper confined aquifers are the source of large volume, municipal and industrial groundwater supplies in the area. These include the Chicot, Evangeline, and Jasper aquifers. The Chicot and Evangeline are the major aquifers in the area and consist of interbedded sands, silt and clays.

The Chicot aquifer system includes the uppermost confined aquifers in the area and generally refers to all Quaternary deposits, including the unconfined alluvial aquifers, the confining Beaumont clay, and the underlying Montgomery Formation, Bently Formation and Willis sand. The thickness of the aquifer increases toward the Gulf from zero at the western edge of the Quaternary outcrop (80 miles from the Gulf) to over 1200 feet at the Gulf (see Figure 3-4 and Plate E1). The approximate altitude of water levels in wells completed in the Chicot Aquifer in the Spring of 1975 is presented on Figure 3-5 and Plate E2.

The transmissivity ranges from zero to about 20,000 ft²/day, with storage coefficients ranging from 0.0004 in the confined area of the aquifer to 0.20 in the northern, unconfined area (Jorgensen, 1975).

The Evangeline aquifer, comprised of Pleistocene deposits, immediately underlies the Chicot. It is the most important source of fresh ground water in the Houston metropolitan area. Although it has a lower hydraulic conductivity than the Chicot, the thicknesses are greater, up to about 2,000 feet near the Gulf of Mexico. The approximate altitude of water levels completed in the Evangeline aquifer in the Spring of 1975 is presented on Figure 3-6 and

Harris-Galveston

Plate E3 The transmissivity is greater than that of the Chicot aquifer over much of the area, ranging from 5,000 ft²/day at the north edge of the plain to 15,000 ft²/day at the Gulf. Storage coefficients range from 0.0005 in the southern confined area to 0.20 in the northern unconfined area (Jorgensen, 1975).

The Evageline aquifer is underlain by the Burkeville confining layer of the Tertiary Flemming Formation. Below the Burkeville is the Jasper aquifer.

Groundwater withdrawal in the region dates back to about 1890. During the past century, pumping of large quantities of water has caused significant declines of up to 400 and 500 feet in the lower Chicot and Evangeline aquifers, respectively.

Recharge of the confined aquifers results primarily from direct infiltration in the aquifer outcrop areas. Only minor vertical recharge occurs through the confining beds overlying the aquifers.

The Harris-Galveston Coastal Subsidence District identifies sixteen water wells within approximately 2 miles of the French Limited site. The well data is presented on Table 3-1 and their locations are shown on Figure (3-8). The minimum depth to the first screen interval for these wells is 200 feet. The closest major water well to the French Limited site is approximately 3,000 feet southeast of the site, and is the one mentioned earlier that is screened at 200 feet. Figures 3-5 and 3-6 show four additional wells screened from 250 to 300 feet that are immediately downgradient of the site.

3.4.2 Local Hydrogeology

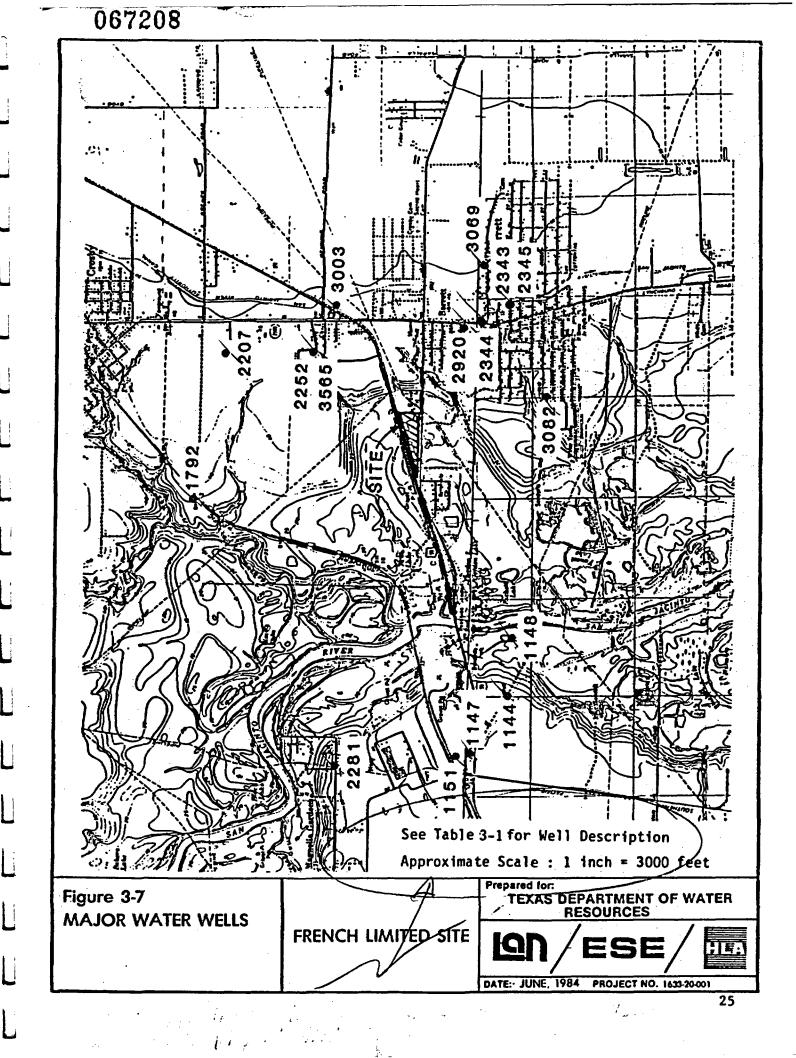

Two aquifers are present within the 155-foot depth investigated for this report: the Upper Aquifer, consisting of Holocene alluvial deposits, and the Lower Aquifer consisting of a sand layer approximately 50 feet thick at a depth of approximately 125 feet. The two aquifers are hydraulically separated by approximately 75 feet of Pleistocene sediments consisting predominantly of clays. Both aquifers are considered a part of the Chicot aquifer.

In the site area, the Upper Aquifer extends from the ground surface to a maximum depth of 55 feet (Elevation -40 feet). The San Jacinto River Valley, which contains the Upper Aquifer, is approximately 2.5 miles wide in the site vicinity. The alluvial deposits consist primarily of fine to medium sands; however, discontinuous silt and clay layers are also present. Because of these discontinuous silt and clay layers, the Upper Aquifer, which is generally unconfined, may have localized areas where confined conditions exists.

Groundwater levels in the Upper Aquifer in the site area are generally at/or near the ground surface with elevations ranging from approximately 7 to 14 feet. In several areas, the groundwater level coincides with the water level in the numerous ponds, pits and marshes in the areas. Based on water levels recorded in monitoring wells at the site during 1983 and 1984, the groundwater level is relatively constant with fluctuations of only a few feet

The hydraulic gradient in the Upper Aquifer in the site area is relatively flat, on the order of 0.001 feet/feet to the north and southwest. Locally, the gradient will be higher over short distances, particularly when there are abrupt changes in the elevation of the ground surface, such as the sand pits, hillsides and creeks. The largest hydraulic gradient observed is between the main pit and the slough to the north, which is on the order of 0.06 feet/feet.

The Lower Aquifer is under artesian conditions with a piezometric surface at approximately Elevation -67 feet. This level is approximately 81 feet below the ground surface and 46 feet above the top of the Lower Aquifer. Based on the thickness of the clay separating the two aquifers and the large difference in water levels, it appears that the two aquifers are hydraulically separated. The gradient appears to be on the order of 0.001 feet/feet toward the south.

Beneath the site, the remainder of the Chicot aquifer is about 400 feet thick, extending to approximately Elevation -500 feet and displays an average transmissivity of about 3,300 ft²/day (Jorgensen, 1975). The piezometric surface of the confined unit near the base of the aquifer beneath the site was about 100 feet below mean sea level in 1975 (see Plate E2).

Part of the second of the seco

to Gradie

The Evangeline aquifer is about 1,500 feet thick beneath the site, with a transmissivity of about 8,000 ft2/day. The piezometric surface beneath the site area was about Elevation -250 feet in 1975 (see Plate E3)

Piezometric levels in the deep confined aquifers beneath the site declined about 150 feet in the Chicot and 250 feet in the Evangeline between 1890 and River Elevation & G.W. Elev. 1970 (Jorgensen, 1975).

3.5 SURFACE WATER

The French Limited site experiences approximately 50 inches of rain per year, with the greatest seasonal rainfall occurring during the summer months. Precipitation only slightly exceeds evaporation.

The general surface water flow pattern in the area is southwest toward the San Jacinto River. The drainage of the site and adjacent areas is poor and generally dominated by man-made features such as roads, ditches, culverts, berms, pits, and garbage dumps or fill areas. The main waste pit and the east pit (see Figure 3-8) are bermed with no regularly flowing outlet. The main waste pit, however, does have an overflow which discharges directly into the fishing hole under U.S. Highway 90. The overflow was installed to prevent overtopping of the berms around the pit during heavy rains, and only flows under those conditions.

The fishing hole beneath the U.S. Highway 90 bridge drains northward and then to the west along the north side of U.S. Highway 90. Flow passes through a series of marshes and culverts, just north of U.S. Highway 90, eventually reaching the San Jacinto River some 6,000 feet to the west. The marsh area east of the French Limited main pit is also in this drainage area. Much of the Sikes Disposal Pits site also drains into this same watershed.

The abandoned sand pit south of the site drains into a channel which enters Rickett Lake some 4,800 feet to the southwest. Rickett Lake is shown in Figure 3-2. The creek is the main natural drainageway for the area and likely influences the near-surface groundwater flow pattern.

The San Jacinto River south of the Lake Houston Dam is under the tidal influences from Galveston Bay. This reach of the river is designated for contact and noncontact water-oriented recreation, as well as the propagation of fish and wildlife. This reach is not used as a domestic water supply (Texas Surface Water Quality Standards, amended 1981).

The flood of May 22-24, 1983 afforded the opportunity to view the site during flooding conditions. Figure 3-9 shows the flow patterns observed the afternoon of May 23 and morning of May 24. The flood peaked the evening of May 23 and was approximately 2 feet above the berm (16 feet above ms1) surrounding the main waste pit at that time. The 100-year flood elevation in the French Limited site vicinity is 28 neet above ms1. (See page 15 - dike elevation = 13.71 to 71.41)

In addition to the May 1983 event the site has flooded in 1969, 1973, and 1979. The potential for waste and contaminated surface water transport during flood events is great. During and shortly after the active years of this site's operation, the contaminant migration caused by flooding was likely greater due to higher suspended solids, more liquid wastes, large amounts of floating sludges and higher waste concentrations in the main waste pit waters. Past flood events have regularly flooded the residences in the Riverdale Subdivision. At this time, the subdivision does not appear to be immediately downstream of the French Limited site, but area residents report that after several of the past floods sludges were transported into the subdivision and remained when the flood waters receded. During the May 1983 flood, small quantities of the floating oily residue were transported southward across Gulf Pump Road.

3.6 AREA LAND USE/POPULATION

The French Limited site is approximately one mile south of Crosby, Texas and one-half mile east of Barrett, Texas. The combined population of the Crosby/Barrett area is approximately 5,250 based on the 1980 census. The two towns serve as small communities to the greater Houston area, with many of the inhabitants working for the industries around the Houston Ship Channel.

The Crosby/Barrett area is primarily residential with some commercial businesses and some sand mining operations along the San Jacinto River and its

1963 Flood

topos

Update

tributaries. Some farming also occurs in the outlying areas. Approximately two miles west of the site, on the western bank of the San Jacinto River, St. Regis operates a pulp/paper mill.

The area around the French Limited site is primarily undeveloped, densely wooded land with large intermittent swampy areas. The area contains many abandoned sand pits which are frequented by area sport fishermen. Southwest of the site is the Riverdale Subdivision (see Figure 3-1) with a residential population of less than a hundred people. Adjacent to the subdivision is an active pipe storage yard, on land that was a landfill operated by Harris County in the late 1960's. Gulf Pump Road which borders the site on the south shows evidence of illegal garbage dumping along the roadside ditches.

Approximately one mile west of the site along the San Jacinto River and one-half mile north of the site along Jackson Bayou are numerous active sand mining operations.

4.0 FIELD ACTIVITIES

4.1 SOIL BORINGS

4.1.1 Selection of Borings and Well Locations

This section presents data for borings and wells installed during three field investigations. During the investigations, twelve soil borings (borings with soil sampling) were drilled and twenty groundwater monitoring wells were installed. The borings ranged in depth from 20 to 155 feet. Two privately owned wells and two wells installed by TDWR were also included in the monitoring program. The location of the borings and wells are presented in Table 4-1, on Figure 4-1 and on Plate B-1.

4.1.2 Drilling and Soil Sampling Methods

The borings were drilled utilizing truck and swamp buggy-mounted rotary wash drilling equipment using water obtained from a Harris County MD50 fire Typh hydrant. Small amounts of drilling fluid additives (non-organic bentonite derivatives) were used in boring B002/GW02, B003/GW03, B005/GW05 and GW12 through GW25 to prevent the borings from collapsing.

Borings BOO1 through BO12 were logged during the drilling operations, and samples of the subsurface soils were obtained for visual classification and laboratory testing. Soil samples were taken at 5-foot intervals to a depth of another 100 feet and at 10-foot intervals thereafter. In boring GW12, samples were taken at 10-foot intervals for the depth of the boring. Soil samples were obtained using a Shelby Tube sampler and various split spoon samplers. The samplers and sampling methods are described on Plate B5 in Appendix B. Wells GW11, and GW13 through GW22 were logged from cuttings and drilling rates attained during the drilling process. 2 collegended to earlier drilling a fail in process.

Soils were classified in accordance with the Unified Soil Classification System presented on Plate B5. A graphical representation of the subsurface strata encountered in each boring is presented on the Log of Borings in Appendix B.

To aid in identifying contaminated soil samples, a photoionization detection (PID) meter was used during the drilling of BOOl through BOll. The meter

detects volatized organics and is sensitive to less than one-half part per million (ppm). The meter was used in place of the pH and specific conductance tests originally proposed in the Work Plan. The PID readings are presented in Appendix B on the Log of Borings. Contaminated soils showed high readings; however, not all readings were indicative of contamination. Based on visual observations, odors, and PID readings contaminated soil samples were found only in borings immediately around the the main waste pit and in boring BOll approximately 100 feet to the southeast of the main waste pit.

Borehole geophysical logs were run on borings BOO1 through BO11, excluding BOO5 and BO10, when the borings were completed to their full depth. The boring was then either converted to a groundwater monitoring well, as described in Section 4.2, or sealed to the ground surface with a cement/bentonite grout. Soil cuttings from the borings were placed in containers, and dumped into the main waste pit so as to prevent possible surface contamination outside the immediate site area.

4.1.3 Borehole Geophysical Logging

The purpose of the geophysical logging was to provide a continuous profile of the subsurface strata, to complement the soil boring logs and to identify possible thin sand and clay lenses that might be missed during the drilling operations. Logging was done using Logmaster equipment. A brief description of each type of log and its interpretation is presented in the following paragraphs.

A resistivity and self-potential log was run in the 4-inch diameter borings prior to reaming or grouting the boring. Boring B005 and B010 were not logged because they were inaccessible to the equipment. Boring B003/GW03 was logged using a natural gamma and a gamma-gamma density probe after the well was installed. To aid in the interpretation of the logs the soil log is presented on the left side of each plate.

The logs showed occasional thin sand lenses in the deeper clay layers particularly in borings B002/GW02 and B006/GW06. It should also be noted that in boring B008 and B009 (near the main waste pit) the Single Point Resistance in the sands is lower than would be expected. This is possibly caused by the presence of inorganic contaminants, or ionizable inorganic compounds.

Single Point Resistance—Single Point Resistence is a measure of the ability of a soil formation to conduct electric current through fluid—saturated pore spaces (resistivity is the inverse of conductivity). At a given temperature, the resistivity of a formation is a function of the geometry of interconnected pore spaces, the percentage of fluid saturation, and ion concentration of the pore fluid. Clay—dominated formations have low resistivities because pore waters are subject to desorption of exchangeable ions from clay minerals. These ions increase the conductivity of the pore water and thereby reduce the resistivity of the formation. Sand dominated formations generally have high resistivities in cases where (1) the sand is "clean" (i.e., essentially free of clay); (2) the pore fluid is "fresh" (i.e., low salinity), and (3) the porosity is low. The magnitudes of resistivities for sand formations are greatly reduced by the introduction of even a small fraction of clay (less than one percent of the total volume). Increasing either the porosity or the salinity of the pore water also lowers the formation resistivity.

Self-Potential--The borehole self-potential log is a measure of natural direct current (DC) voltages that are generated within the borehole. Electrochemical potentials are produced when there is a difference in ionic concentration, between the borehole fluid and the formation water. In a permeable formation. a potential forms where the borehole fluid and formation water come in contact. The differences in ion mobilities within the two solutions cause an electrical charge imbalance at the contact, and this imbalance produces a potential that is known as the liquid junction potential. In addition, a potential is formed across a clay-sand boundary. The clay acts as a selective membrane, rejecting anions but allowing cations to diffuse. The resulting charge imbalance at the boundary is known as the membrane potential. These two potentials are additive. When the borehole fluid is less saline than the formation water, a negative potential is measured opposite a porous sand or gravel bed. A positive potential can result when the borehole fluid is more saline than the formation water. Potentials measured opposite clays serve as a baseline for self-potential deflections.

Natural Gamma--This log measures the natural radioactivity of the formations encountered in the borehole. Gamma radiation occurs in the high energy range of the electromagnetic spectrum. Nearly all gamma radiation is emitted from

the unstable isotope potassium 40 which tends to concentrate in clay minerals. Interpretation of gamma intensity in terms of clay content is qualitative; a high gamma intensity (counts per second) indicates high clay content (clay-rich soil), and low gamma intensity indicates low clay content (suggesting a sandy soil).

Gamma-Gamma Density--The gamma-gamma density logging utilizes a probe containing an element of 125 m/c of Cesium 137 at the bottom of the probe and sodium iodide crystal detectors 8.125 inches above the source. Sands adsorbs more energy than clays and therefore show a lower radiation count. On the E-logs graph, the plot was reversed so as to have the same direction as the natural gamma readings (see Plate B-11, Appendix B).

4.1.4 Physical Soil Analysis

Soil samples from the borings were taken to HIA's Houston laboratory for selected testing and storage. Laboratory tests were performed in order to evaluate the physical properties of the site soils for use in contaminant transport modeling and analysis as well as for correlation with field tests. The tests performed and the standards used are presented in Table 4-2.

The test results are also presented on the boring logs and in Appendix C as described on Plate Cl. Particle size analyses are presented on Plates C2 through Cl2. The grain size distribution range for the clean sands and silty sands/sandy silts are presented on Plates C2 and C3, respectively. The percent passing the No. 200 sieve (silt fraction) is also presented on the boring logs.

The Atterberg Limits (Liquid Limit and Plasticity Index) are presented on Plasticity Charts, Plates Cl3 through Cl5, as well as on the boring logs. Specific gravity and laboratory permeability results are presented on the boring logs. The results of the laboratory tests for each Formation are summarized on Tables 4-3, 4-4 and 4-5.

Tables 4-3 through 4-5 presents the laboratory data on the alluvium. The alluvium consists of clean sands, silty sands, sandy silts and clays. The sands are medium dense; their moisture contents vary between 11 and 19 percent

and their dry density between 97 and 116 pounds per cubic foot (pcf). The sands are generally fine to medium grained and remolded permeability tests show vertical permeabilities on the order of 10^{-3} cm/sec. The alluvial clays are stiff to very stiff and have moisture contents that varied from 14 to 35 percent. The dry densities ranged from 90 to 114 pcf. The measured vertical permeability of clay ranged from 10^{-4} to 10^{-6} cm/sec.

The Beaumount clays are very stiff to hard with moisture contents between 17 and 33 percent, and dry densities between 89 and 107 percent. The clays are highly plastic with measured vertical laboratory permeabilities on the order of 10⁻⁷ cm/sec.

The Lower Aquifer at a depth of approximately 125 feet consists of a very dense, fine-grained silty sand. Permeabilities in this layer are estimated to be on the order of 10⁻³ cm/sec.

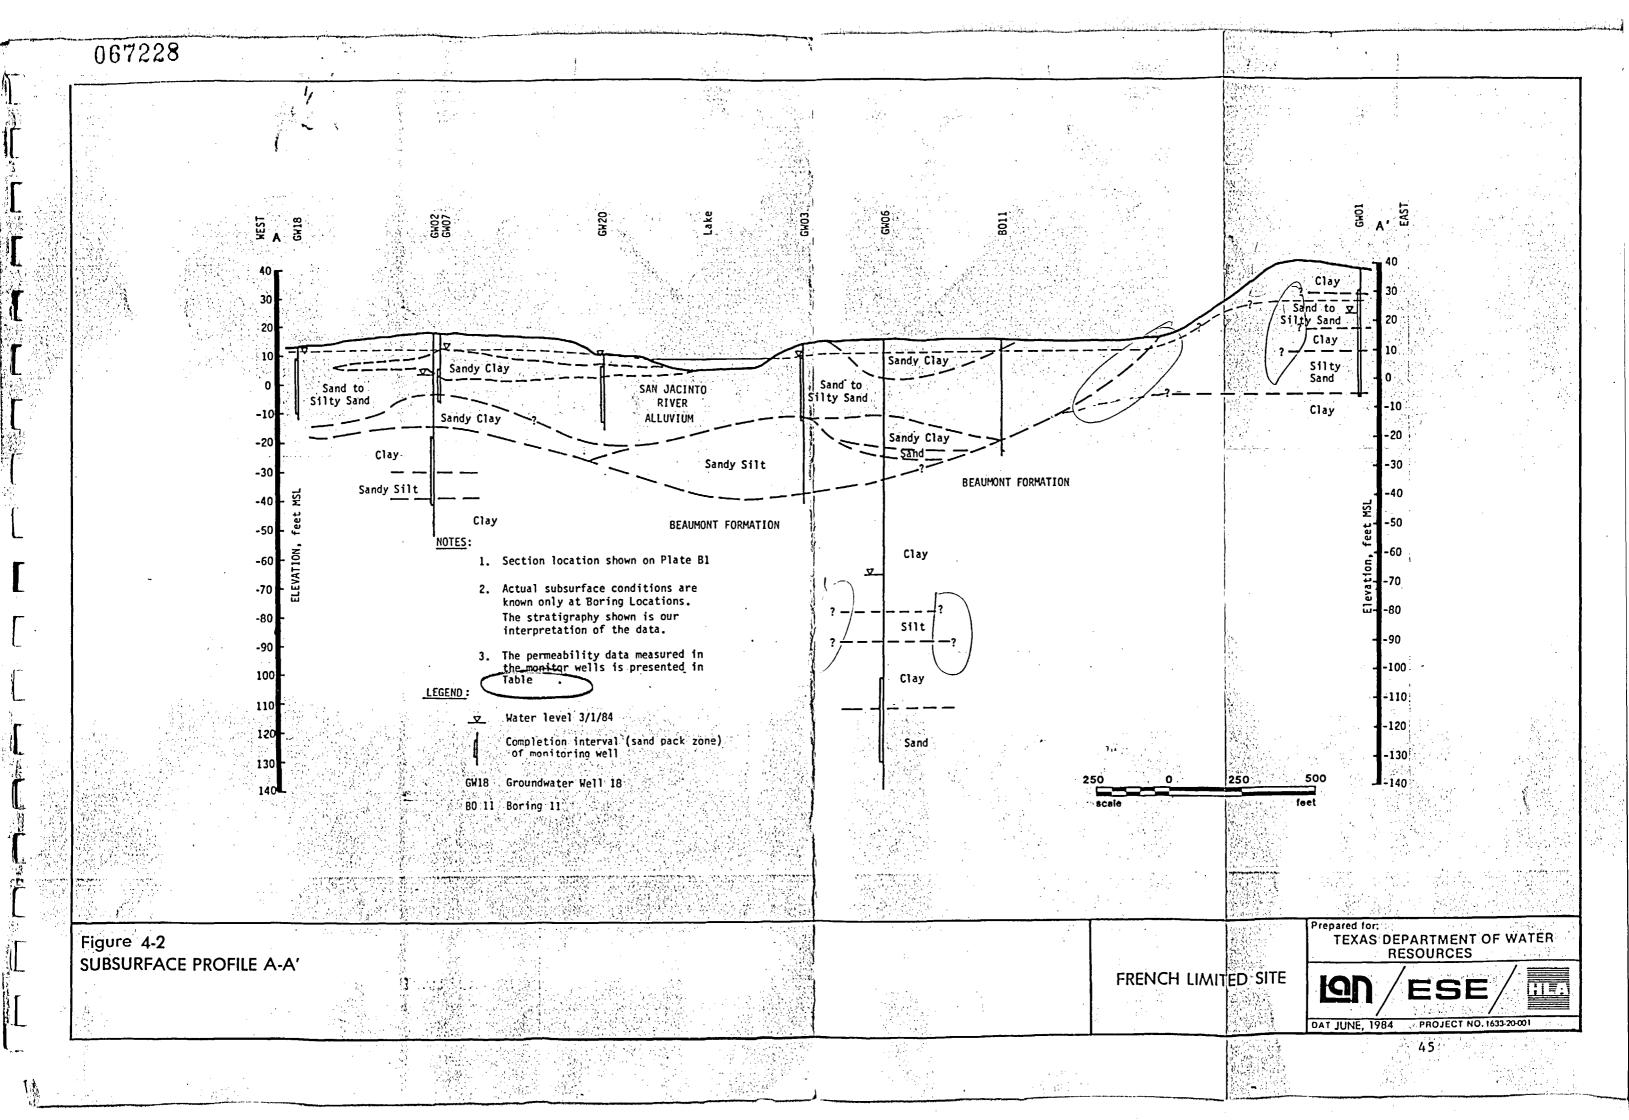

4.1.5 Assessment

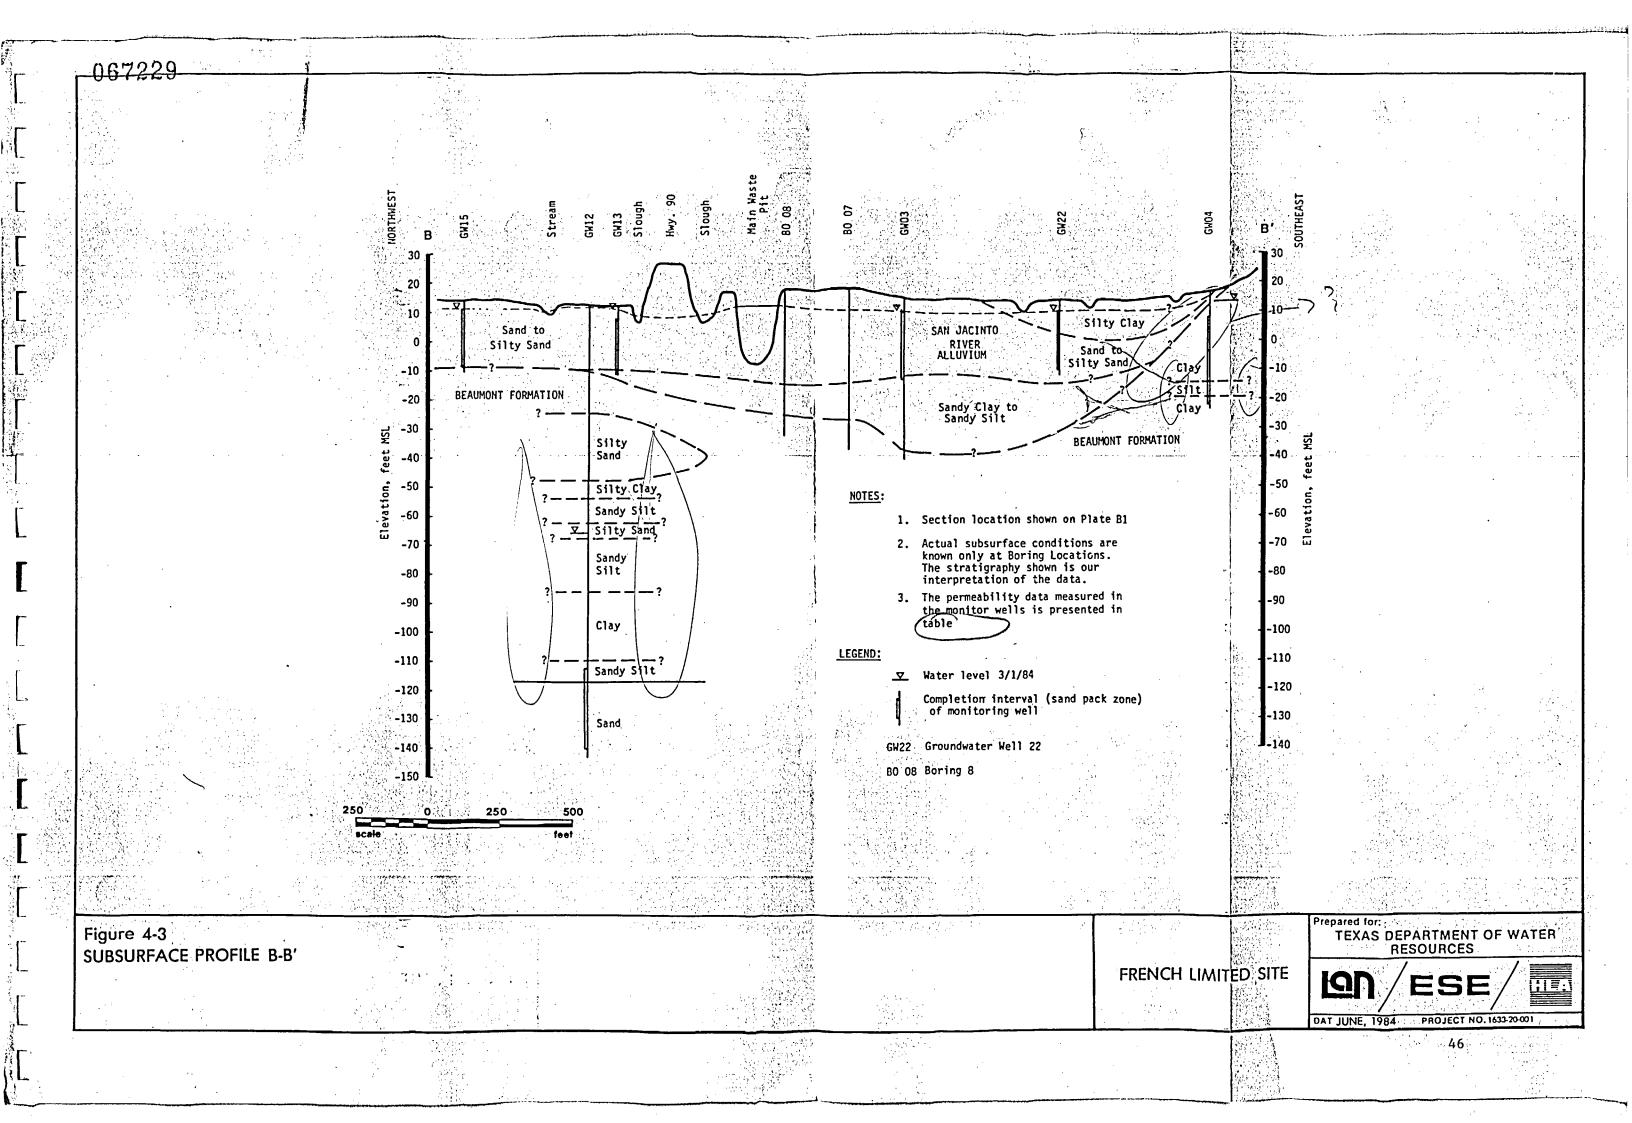

Based on the exploration borings, geophysical logs and physical soil tests, the subsurface soils are interpreted as follows. Within the site area and depth of interest to the project, there are two types of soil deposits; the relatively permeable San Jacinto River alluvium and the underlying relatively impermeable Pleistocene deposits. The vertical and lateral extent of the alluvium in the site is shown on the subsurface profile presented on Figures 4-2 and 4-3 (also see Plates B-3 and B-4). The location of these profiles is shown on Figure 4-4 (also see Plate B1).

The meandering San Jacinto River eroded the underlying Pleistocene clay soils to depths of 20 to 55 feet in the site area. During the erosion process, the river is also filling the eroded valley with point bar, channel and overbank deposits.

As a result of this depositional environment, the alluvium may be characterized as follows:

 The alluvium consists predominantly of sand, with some silt and clay layers which have been deposited during different stages of flow from San Jacinto River;

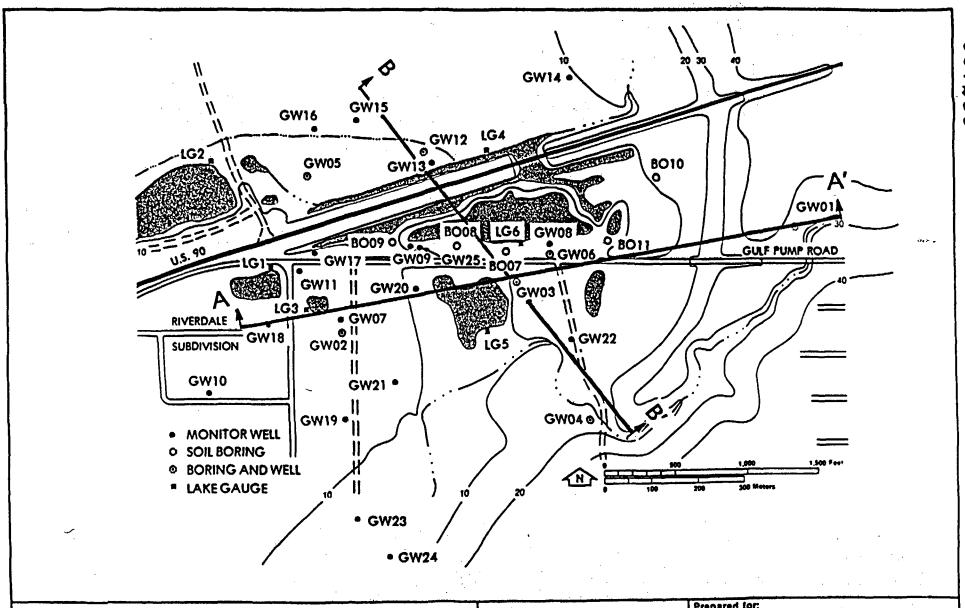

Figure 4-4

DATE: JUNE, 1984 PROJECT NO. 1633-20-001

- 2. The alluvium is relatively permeable and should be considered continuous throughout the river valley; however, layers of lower permeable silts and clays also exist in the deposit;
- 3. The contact between the alluvium and the underlying Beaumont Formation is irregular because of the meandering of the San Jacinto River; and
- 4. The measured vertical permeability in the alluvial sands is on the order of 10⁻³ cm/sec. Typically, the horizontal permeability is much larger than the vertical permeability in alluvial deposits. The horizontal permeability in the alluvial sands is estimated to be on the order of 10⁻² cm/sec.

The alluvial deposits are underlain by Pleistocene sediments to great depths. The Beaumont Formation is the first Pleistocene deposit underlying the alluvium and it is predominantly clay with some discontinuous silt and sand layers. The clays are generally highly plastic with a stiff to very stiff consistency. The clays have a blocky secondary structure with occasional slickensides.

Sand and silt layers in the clay are typically less than a few feet thick.

Borings BOO6, BO12 and GW25 were drilled in the site area to the first significant sand layer in the Pleistocene clays. In boring BOO6, a very dense sand layer was encountered at a depth of 127 feet that extended to approximately 155 feet (bottom of boring). The sand is fine grained with some silt. Permeabilities are estimated to be on the order of 10⁻³ cm/sec.

Based on visual observation, odor and organic vapor readings with a photoionization detector (PID) contaminated soils samples from the borings were observed only in the upper 25 feet and only in borings around the perimeter of the main waste lagoon including boring BOll to the southeast. Positive PID readings were noted at BOO6, BOO8, BOO9, BOll and GW25. No soil contamination was physically observed in the remaining borings.

4.2 GROUNDWATER MONITORING WELLS

4.2.1 Installation and Development

Select borings were converted to groundwater monitoring wells by reaming with either a 4-inch or an 8-inch diameter bit to the desired depth. Immediately after reaming, a 2-inch or 4-inch diameter, threaded, flush-joint PVC casing

was set in the boring. The bottom portion of the casing was screened and set so as to penetrate the bottom of the pervious sand stratum. The screened portion was machine slotted at 0.02-inch widths and was wrapped in geotextile filter fabric (Fibertex, grade 150).

After setting the casing to the desired depth, the boring was flushed of drilling fluids by pumping clean water down through the casing and out through the screen and a spring-loaded check valve at the bottom of the casing.

Flushing continued until the return flow of water was free of significant quantities of drilling mud additives or natural mud. For shallow wells, 300 to 500 gallons of clean water was typically used while 600 to 800 gallons were used on the deeper wells.

After flushing, the annulus of the screened casing was backfilled with a medium to coarse sand. After the sand backfill was placed, the remaining portion of the annulus was filled with a cement/bentonite slurry. On shallow wells, the slurry was poured from the ground surface while on the deep wells it was pumped through a tremie pipe. Vented plastic caps were placed on the PVC casing, and locking 5-foot long metal protector casings were set around the wells. The protective casings were then concreted in place. Details of the well construction are presented on Table 4-6, on the Boring Logs, and on the Eubsurface Profiles in Appendix B.

The wells were developed by removing approximately 3 to 11 times the volume of water in the casing. As a minimum, the wells were purged until the water clarity significantly improved. The amount of water in each well is presented in Table 4-6. As an additional aid in evaluating the well's development, the conductivity of the evacuated water was measured in the wells installed in April 1983. These conductivity readings remained relatively constant during the development.

Most of the wells were developed by evacuating the water from the well using either a 20 cfm or a 175 cfm air compressor. A 3/4-inch air hose lowered to the bottom of the well maintained approximately 85 to 100 psi during development. The water obtained from wells GW01 through GW07 was discharged into barrels by using an inverted U-shaped diverter placed over the top of the

casing. The volume removed was recorded and then placed in the main lagoon to prevent contamination of the area around the well. Wells GW05, GW12, GW14R, GW23, GW24 and GW25 were developed by bailing.

4.2.2 Monitor Well Tests

Slug tests were performed on wells GWO1 through GWO7 in order to evaluate the hydraulic conductivity (coefficient of permeability) of the screened aquifer. The "slug" consisted of a sand-filled water-tight section of 2-inch diameter PVC casing approximately 5 feet long.

The slug was quickly lowered into the well, causing a rise in water level equal to the displaced volume of water. The water level immediately began dropping and was allowed to stabilize. With rapid removal of the slug, the water level was suddenly lowered and recharge began. During the test, water level versus time measurements were taken using a pressure transducer placed approximately 10 feet below the water surface. The pressure transducer was sensitive to 1 millivolt, which corresponds to a 0.06 foot change in water level. Readings were taken manually as well as with a strip-chart recorder that provided a continuous graph of the transducer readout with time. To better substantiate the results, the water level change with time for both the sudden addition and removal of the slug was recorded.

A graphical plot of the slug test data is presented in Appendix D.

Slug test data for fully or partially-penetrating wells in unconfined aquifers (wells GWO1, GWO3, GWO5 and GWO7) were reduced using the procedure developed by Bouwer and Rice (1976). Data for wells GWO2, GWO4 and GWO6 were reduced using procedures for confined aquifers developed by Cooper, Bredehoeft and Papdopulos (1967). The calculated permeability of the screened aquifers is presented in Table 4-7 and in Appendix D.

4.2.3 Staff Gauges

During the December 1983 field investigation, staff gauges were constructed and set in the various bodies of water in the site area. The gauge locations are shown on Figure 4-5, Groundwater Contours 12-7-83. The water level readings for the monitoring period are presented on Table 4-8. Water levels on May 17, 1984 are shown on Figure 4-6.

4.2.4 Groundwater Measurements

Groundwater measurements were taken in the monitoring wells over a one-year period (between April 1983 and May 1984). A complete listing of all the dates and water levels is presented in Table 4-9. Hydrographs of the monitor wells are presented on Figures 4-7 through 4-11 and in Appendix E.

There are sixteen wells screened in the alluvial sediments and five wells (GWO1, GWO2, GWO4, GWO6 and GW12) screened in the Pleistocene deposits, two of which (GWO6 and GW12) are deep wells screened in the first significant sand layer below the alluvium (well GW25 was drilled in May 1984 to replace GWO6). Over the 13-month monitoring period, the maximum and minimum recorded groundwater fluctuation in the wells screened in the alluvium was 3.51 feet and 0.49 feet, respectively. The wells in the upper Pleistocene deposits had fluctuations between 0.91 feet in well GWO1 to 3.73 feet in well GWO4. The two deep wells, GWO6 and GW12, had fluctuations of 2.45 feet and 0.97 feet, respectively. The water level fluctuations were compared between wells as an aid in determining if there are confined layers in the alluvium and if the silt and sand layers in the Pleistocene Formations are hydraulically isolated from the alluvium.

Two of the wells (GW14 and GW20) are located in marshes and when there was standing water in the marshes, the water level in the wells corresponded approximately to the surface water level.

4.2.5 Assessment

The groundwater system in the French Limited site area is assessed as follows. The site is underlain by permeable river alluvium that extends to maximum depths of approximately 55 feet. This alluvium comprises the Upper Aquifer which is generally an unconfined system throughout the site area. Groundwater levels in the Upper Aquifer are generally near the ground surface. Groundwater flow in the Upper Aquifer is confined to the alluvium by the relatively impermeable Pleistocene clay deposits which underlie the alluvium and form the east valley wall. The Pleistocene deposits within 155 feet of the ground surface (maximum depth explored for this investigation) form an Aquitard which restricts downward groundwater migration from the alluvium. The Pleistocene deposits generally consist of low permeability clays; however, some thin silt

- 2. GWO6 was replaced with GW25 on May 15, 1984.

and sand layers are present in the clays. The first significant sand layer in the site area (about 30 feet thick as shown in GWO6) is at a depth of approximately 125 feet. Subsurface profiles through the site area showing the extent of the alluvium (Upper Aquifer) and the Pleistocene (Beaumont Formation) deposits are shown on Figures 4-3 and 4-4, and in Appendix B.

42 64-96

The piezometric water level in this deep sand layer (referred to as the Lower Aquifer) is approximately 80 feet below the ground surface. The 75-foot difference in water levels between the Upper and Lower Aquifer indicated the two are hydraulically isolated. Another indication of hydraulic isolation between the two aquifers is the water level fluctuations. The Upper unconfined aquifer has larger relatively rapid water level fluctuations because it is recharged locally from the surface. Fluctuations in the Lower Aquifer are smaller and of longer duration. The majority of the monitoring wells are screened in the Upper Aquifer because the waste pit is located in the alluvium and the Upper Aquifer is essentially hydraulically isolated from lower confined aquifers by the Pleistocene deposits. The monitoring wells and lake gauges were used to prepare the two groundwater contour maps presented on Figures 4-5 and 4-6 and in Appendix E. The groundwater contour maps are used to determine the gradients and direction of groundwater flow. The direction of flow is perpendicular to the groundwater contours and the hydraulic gradient is the change in head between two points on a flow line divided by the horizontal - which sand , distance between the two points.

The groundwater contour maps show the groundwater flow from the main pit to be radially outward in all directions (i.e. the pit is recharging the groundwater). Beyond the berm surrounding the pit, the groundwater flow toward the east is restricted by the Pleistocene clays and the higher piezometric water levels in the silt and sand layers (see wells GWOl and GWO4). North of the pit on the northside of U.S. Highway 90, the hydraulic gradients are very flat (less than 0.001). Four of the wells on the north side of U.S. Highway 90 had water levels above the elevation of the slough indicating groundwater flow from the north toward the slough. The fifth well GW14R had water levels slightly lower than the slough which indicates flow from the pit area toward the northeast. The higher groundwater levels in the Riverdale Subdivision prevent groundwater flow in a westerly direction from the pit. South of the

pit, the groundwater levels gradually drop toward the southwest in a fairly narrow zone between the valley wall on the southeast and Riverdale Subdivision on the northwest. The groundwater flow beyond the investigation area is unknown but is likely toward the San Jacinto River. Thus, groundwater migration from the French Limited site is predominantly toward, the south.

The groundwater velocity, using Darcian flow, is determined by multiplying the coefficient of permeability by the hydraulic head. The groundwater velocities at several locations on the site were computed by using a permeability of 3×10^{-2} cm/sec for the alluvial sands. The gradient used and velocities calculated are presented on Table 4-10.

These velocities and gradients are for existing conditions at the site. Pumping from area sand pits in previous years probably resulted in different gradients, flow directions and higher velocities than now observed. Therefore, the extent of the contaminant plume cannot be located using the present gradients and velocities. The better indicator would be groundwater analysis from monitoring wells. In addition, the permeability of $3x10^{-2}$ cm/sec used for the alluvial sands is considered a representative horizontal permeability for sands with only trace fines. The clay, silt and silty sand layers in the alluvium have lower permeabilities.

The groundwater flow path from the French Limited site appears to pass beneath the southern portion of the Old Harris County landfill located east of Riverdale Subdivision.

The Pleistocene deposits underlying the Upper Aquifer are predominantly clay with occasional thin discontinuous silt and sand layers. The first significant sand layer in the Aquitard is at a depth of approximately 125 feet. The gradient between the Upper and Lower Aquifers is approximately 10 and by conservatively using a permeability of 10^{-/} cm/sec, the vertical groundwater velocity from the Upper to the Lower Aquifer is approximately 0.1 feet/year.

4.3 GROUNDWATER SAMPLING

4.3.1 Groundwater Sampling Methodology

Twenty-eight new monitor wells, two existing monitor wells, and two residential wells in the Riverdale Subdivision were sampled (see Table 4-1 and Figure 4-12 for exact locations). The monitor wells were sampled after evacuating a volume of water equal to three to five times the volume in the well casing. This water was pumped into drums, using a large peristaltic pump or a construction pump with a PVC dip tube. The samples collected in April 1983 were taken with a variable speed peristaltic pump set at a slow pumping rate (400 to 600 ml/min). A new length of Teflon tubing was used at each well. Sample fractions needed for volatile organic analysis were obtained using a new PVC bailer. All samples collected in November 1983 were taken with PVC bailers.

GW06 and GW12 were evacuated and sampled using a PVC bailer because the water level was some 80-feet below the ground surface, and the peristaltic pump was not able to pump at this head.

The residential wells were sampled at their pump houses. In both cases, the faucets were located downstream of the holding tanks.

4.3.2 Chemical Results

The potential exists for the migration of contaminants in surface and ground waters. Since the waters can become a supply for human consumption, serious long-term health effects can result. Therefore, a comparison between contaminant levels and human health criteria is appropriate.

In April 1983, the background well GWO1 (see Figure 4-12) exhibited chlorobenzene at 7 micrograms per liter (ug/1) or parts per billion (ppb) and at 6 ppb in the duplicate sample. A trace of phenol (5 ppb) and a relatively high conductivity of 1,301 micromhos per centimeter (umhos/cm) were observed in GWO1 (Table 4-11). Mercury was observed in GWO1 at trace levels (0.7 ppb) but was not found in any of the other wells.

The groundwater sample taken in April 1983 from shallow well GW08 located near the site exhibited significant levels of GC/MS volatiles, phenols (100 ppb), and a conductivity of 2,380 umhos/cm. Benzene was found in GW08 at 180 ppb,

available shortly.

which is approximately 30 times above the proposed 10^{-5} incremental cancer risk human health criterion of 6.6 ppb (see Appendix F). Benzene was also seen in GW09 at 100 ppb. Carbon tetrachloride in GW08 at levels of 44 ppb exceeded the human health criterion of 4.0 ppb. Well GW08 also contained significant levels of 1,2-dichloroethane (440 ppb), which exceeds the criterion of 9.4 ppb. Vinyl chloride at 39 ppb was also present in GW08, which is double the health criteria of 20 ppb. Other volatiles (chloroform, methylene chloride, tetrachloroethene, and trichloroethene) were present in GW08 at levels exceeding human health criteria.

TDWR and USEPA sampled wells GW08 and GW09 on October 7-9, 1981, and found substantial levels of volatile organic compounds (see Table 4-12). The levels of contamination in April 1983 were similar for many of the compounds detected. Seasonal hydrologic factors could account for the concentration differences observed.

Deep well GW06 was sampled in April and again in November 1983 (see Table 4-13) and showed much lower TOC and conductivity levels than GW08 and GW09. The pH was 9.2 in April and 9.3 in November, whereas the shallow aquifer had pH in the range of 5.4 to 7.1. Deep well GW12 (see Table 4-11) had a pH of 8.8, almost as high as GW06. This high pH is common for the deeper aquifers in the area. GW02 into the Aquitard had a pH of 7.8, and the two samples in the Riverdale Subdivision (GW10--52 feet, GW11--87 feet) had pH of 7.7 and 7.6, respectively. Preliminary results from deep well GW06 indicated traces of four GC/MS volatiles. Upon further investigation the casing was found to have a split in it potentially allowing contaminated shallow ground water to enter the casing. The well was pumped extensively to remove any contaminants that could have be entered the lower aquifer, the casing drilled out to the clay layer and then the hole was sealed from the bottom up with a cement-bentonite slurry. A new deep well GW25 was drilled in the immediate area, and chemical results will be

The deep well GWl2 installed in November 1983 north of U.S. Highway 90 was analyzed by GC/MS for volatiles, but nothing was found above detection limit. The shallow well GWl3 adjacent to GWl2 had a pH of 6.8, and exhibited no contamination in the GC/MS volatile fraction either.

Three other shallow wells (GW14, GW15 and GW16) were installed in November north of U.S. Highway 90. Well GW14 exhibited 1 ppb phenol, 52 ppb TOX, and was free of GC/MS volatile contamination. GW15 showed 61 ppb TOX (38 ppb in the duplicate), and traces of two compounds in the GC/MS volatile scan:

1,1-dichloroethane at 2 ppb (2 ppb in the duplicate); and vinyl chloride at 6 ppb (5 ppb in the duplicate). GW16 further west of GW15 was free of GC/MS volatile contamination. Well GW05 north of U.S. Highway 90 was free of GC/MS detectable contamination in both the April and November samples (see Table 4-13).

Wells GW02, GW03, GW04, and GW07 are located south of Gulf Pump Road. In April 1983, shallow well GW07 exhibited 6 ppb of chlorobenzene. The shallow well GW07 exhibited 6.3 ppm TOC and 184 ppb TOX, while the adjacent deep well showed no detectable levels of either of these indicators. GW03, immediately south of Gulf Pump Road, exhibited 20 ppm TOC and 94 ppm TOX in April. The November sample from GW03 was analyzed by GC/MS for volatile compounds (see Table 4-13) and showed benzene at 22 ppb; 1,1-dichloroethane at 23 ppb; 1,2-dichloroethane at 25 ppb; trans-1,2-dichloroethene at 8 ppb; and vinyl chloride at 5 ppb. GW04 exhibited a high conductivity (1,109 umhos/cm) but otherwise appeared uncontaminated. Well GW04 is screened in the same formation as the background well (GW01) which also exhibited a high conductivity.

Six more shallow wells (GW17 through GW22) were installed south and west of the French Limited site in November 1983 to better evaluate groundwater gradients and chemistry. GW17 at the far west end of the site showed 2 ppb 1,2-dichloroethane. GW18 in the Riverdale Subdivision was free of GC/MS volatile contamination. GW19, at the edge of the old Harris County landfill southeast of Riverdale, showed 23,200 ppb TOC and a conductivity of 1,731 umhos/cm, but showed no contamination in GC/MS volatile fraction. GW20, south of Gu1f Pump Road near the west end of the main pit and east of the old landfill, showed a TOC of 35,800 ppb, benzene at 6 ppb, and chlorobenzene at 4 ppb. Well GW21, southwest of the lake south of Gu1f Pump Road and screened through the landfill, had higher levels of contamination than GW20: 82,900 ppb TOC; 250 ppb TOX; 11 ppb benzene; 2 ppb chlorobenzene; and 2 ppb 1,2-dichloroethane. GW22, east (and upgradient) from GW21, was free of GC/MS volatile contamination.

The residential wells GW10 (87 feet deep) and GW11 (52 feet deep) located in Riverdale Subdivision were sampled in both April and November 1983. Samples from both wells were analyzed by GC/MS for volatile organics in November and did not show any contamination. Well GW11 was analyzed for the GC/MS acid and base/neutral fractions in April, but nothing was detected in these samples.

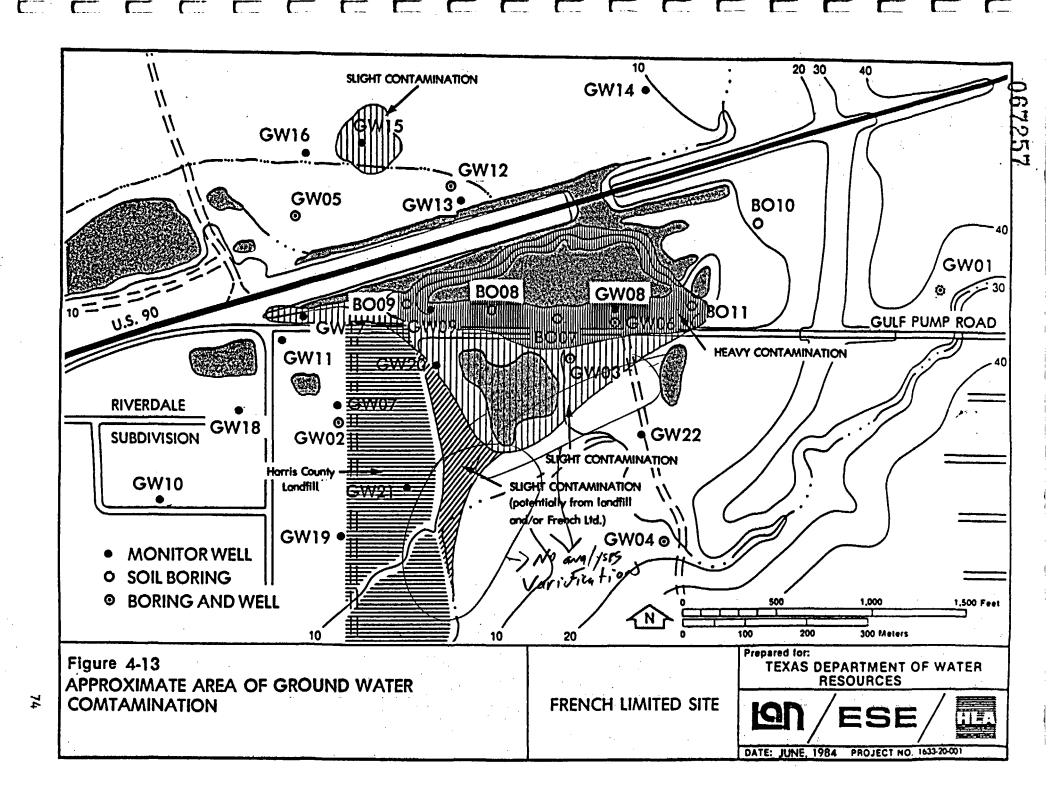

4.3.3 Assessment

Geotechnical and chemical data indicate that ground water in the immediate pit area is heavily contaminated. South of the site this heavily contaminated area extends approximately 200 feet from the pit or just beyond Gulf Pump Road (see Figure 4-13). Groundwater wells GW08 and GW09 in this area had elevated concentrations of over a dozen volatile organic compounds similar to those found in the main pit sludges. It appears that ground water around the pit is becoming heavily contaminated through some leaching action of the main pit sludges.

Just beyond this heavily contaminated area is an area of less contaminated ground water (see Figure 4-13). Groundwater wells GW03, GW20 and GW21 all show lower concentrations of several of the same compounds seen in wells GW08 and GW09. The extent of this less contaminated area is unknown, but lies somewhere between GW21 and GW23.

The old Harris County landfill adjacent to the Riverdale Subdivision appears to have contributed contamination into the Upper Aquifer. Groundwater wells in and adjacent to the landfill, GW07 and GW19 on the west side, GW20 and GW21 on the east side, and GW23 on the south side exhibited elevated concentrations of one or more of the following: TOC, benzene, chlorobenzene arsenic and barium. Arsenic and barium were not found at the French Limited site and the chlorobenzene levels found at the site were minimal. These findings indicate the landfill is contributing to groundwater contamination south of the French Limited site.

Unregulated and indiscriminate dumping of wastes in the area, both past and present, could have resulted in the dumping of some hazardous wastes in the old landfill. A Texas Department of Water Resources District 7 representative reported that standing water in the trenches at the old landfill had an oily film and a chemical odor (TDWR Memo, April 1984).

Two additional areas of slight groundwater contamination were found: one along the slough west of the pit and south of U.S. Highway 90, and the other northwest of the site around groundwater well GW15.

Well GW17, west of the main pit and north of Riverdale Subdivision, showed a trace of volatile organic contamination. This appears to be a result of leaching of the sludges which were in the slough west of the main pit but south of U.S. Highway 90. If this is the case, all the ground water under the slough likely contains similar contamination. The removal of sludges in 1981 has eliminated much of the original source of this contamination.

Well GW15, several hundred feet north of U.S. Highway 90 northwest of the main pit, showed traces of two volatile organic compounds similar to those found in the pit sludges. The wells closer to the main pit, GW12 and GW14, indicated no detectable organic contamination. In addition, the wells further away from the French Limited pit but closer to the Sikes Disposal Pits, GW05 and GW16, showed no organic contamination. Well GW05 did indicate some metals contamination (13 ppb chromium) when sampled in April 1983.

All of the wells in the vicinity of the site indicate the presence of TOX at levels over that of the background well GWOl. Although many of the wells did not indicate contamination by specific organic compounds, the incidence of TOX in the ground water indicates probable contamination by synthetic organic compounds. At this time, however, no TOX criteria have been set for drinking water or surface water, and no concentration limit has been established for alarm levels of TOX.

In summary, heavily contaminated ground water appears to extend south of the main pit to Gulf Pump Road and up to 200 feet radially out from the pit in all other directions. Ground waters between Gulf Pump Road and the drainageway to the south (approximately 700 feet) are less contaminated. Contamination in this area, however, can not be attributed solely to the French Limited site. There are strong indications that the Harris County landfill is contributing to the groundwater contamination in this area.

There is also an area of slight groundwater contamination along the slough west of the main pit and south of U.S. Highway 90 and an unexplained pocket of south contamination northwest of the site near GW15 (see Figure 4-13).

4.4 BATHYMETRY/SUB-BOTTOM PROFILING

4.4.1 Methodology

The French Limited pit was originally formed by the dredging of sands out of the pit. Because the pit remained filled with water during this sand mining operation, the exact depths of excavation or the pit volume are unknown. After about 1965, the pit was used for disposal of industrial waste.

A bathymetric and sub-bottom profile survey of the French Limited disposal site was conducted on April 12-14, 1983 to characterize the main waste pit morphology, determine the volume of water in the pit, and define the areal distribution and volume of sludge in the lagoon.

The survey was conducted from a small boat using a Del Norte trisponder microwave positioning system, an Esterline Angus Model PD2064 digital data logger, a Raytheon Model D719 fathometer, and a Klein Model 531 combination side-scan sonar and sub-bottom profiling system.

Horizontal positioning was accomplished using a Del Norte Trisponder microwave system. The positioning system was coupled to the digital data logger which automatically recorded the position of the boat every 30 seconds while the boat moved at speeds of 2 to 4 mph (1 to 2 m/sec). After the survey, track lines showing the boat position at all times were plotted by computer. Survey transect lines were made at sufficient spacing to provide complete coverage of the lagoon. Areas of special interest were surveyed with closely spaced track lines, and sometimes tracks were repeated to increase resolution.

The fathometer, which has an accuracy of ±0.1 foot, and the positioning system, which is accurate to ±3 feet, were calibrated the morning of the survey. The sub-bottom and side-scan sonar system are factory calibrated.

In November 1983, sediments in the main pit were sampled with a vibracore device to further evaluate sludge thicknesses. Cores COOl through COlO were

Jarisie

collected from the main pit, while three additional cores (COII through COI3) were taken from the lake south of Gulf Pump Road to determine the appearance of sediments. Two composite samples of cores from the main pit (SE25 and SE26) were collected and chemically analyzed for pollutants. The chemical findings are discussed in Section 4.6.2.

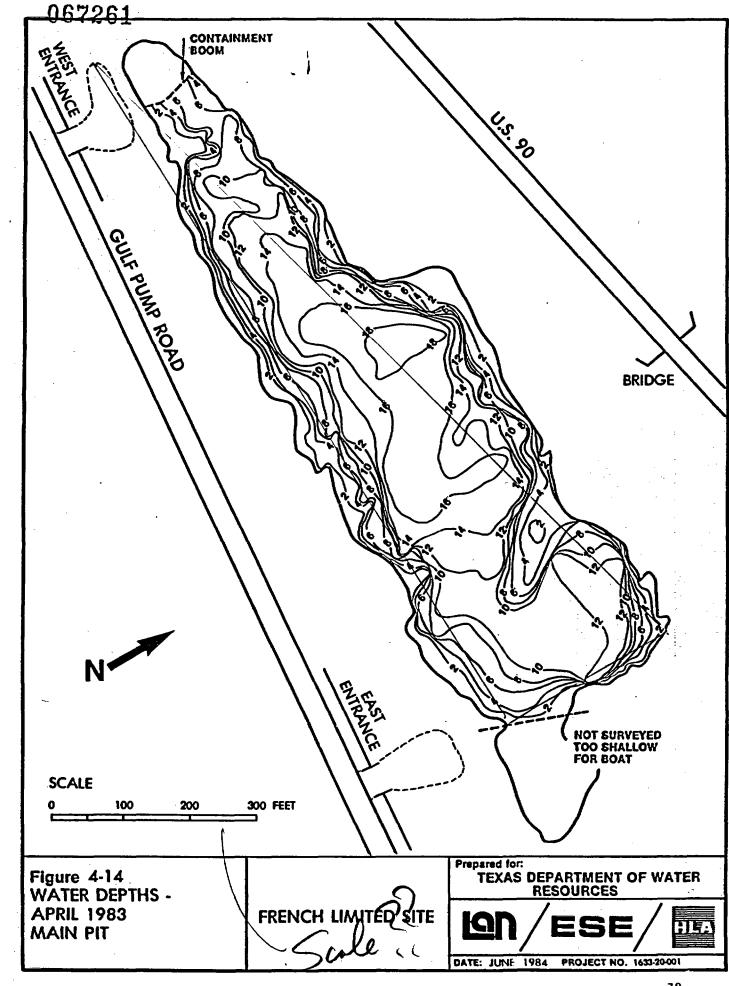

4.4.2 Results

The bathymetric map showing water depths in the French Limited main pit is shown in Figure 4-14. The deepest area in the pit exceeded 18 feet in mid-April 1983, when the water in the pit had an approximate surface elevation of 10.6 feet above mean sea level. The average depth of water across the Julyou say entire pit was 10.6 feet at the time of the survey. The pit contained # BAC. approximately 24.5 million gallons of water.

Two small areas at the extreme east and west ends of the pit were not included in the survey. At the east end, an area of about 0.5 acre was too shallow for the boat and survey equipment to enter. The water depth in this area was about one foot. At the far west end of the pit, a containment boom holding back floating sludge prevented measurements. The area behind this boom is about 0.15 acre, with a water depth of about 4 feet. The water volumes in these areas are included in the volume estimates above.

Sub-bottom profiler records exhibited acoustic imagery typical of extremely fine-grained sediment's or highly organic sediments at the water/bottom interface. Below the interface, interbedded, unconsolidated sands were observed to depths of more than 50 feet below the lagoon surface. The records were indicative of interbedded sands or fine-grained, silty sands interspersedwith thin clayey sand layers. Lydrocarbon or organic sludges appear as acoustic haze on the sub-bottom profiler record. The sludge areas detected by the sub-bottom profiler indicate that the sludge is concentrated in depressions in the lagoon bottom. The sludge is recognized as the acoustic shadow immediately above the first acoustic return from the underlying sand surface.

Evaluation of acoustic records indicate that the sludge within the main pit is concentrated or pooled in the deepest areas (see Figure 4-14). Numerous sludge & dumps or deposits exist around the banks at or near the water edge. In

addition to the material that may have been disposed directly into the water, these deposits on the banks apparently seep or flow downgradient into the pit. The lack of significant accumulations of sludge on the submerged slopes of the pit suggests that the sludge ponds at the bottom through gravity flow. Probing with rods along the south bank near the east entrance indicated that the sediments were a high viscosity material. Sampling with a PVC pipe in April was not successful.

In November 1983, the water elevation in the main pit was about 11.6 feet above mean sea level, or about one foot higher than in April. The ten core samples (COO1 through CO10) taken from the main pit in November 1983 are shown in Figure 4-14. A summary of the findings at each coring station is presented in Table 4-14.

In general, the coring observations confirmed the acoustic measurements made in April 1983. However, coring at some locations (such as COO3, COO4, COO7 and COO9A) seemed to yield sludge thicknesses greater than the acoustic measurements. The acoustic measurements had no way of yielding information on the sands below the sludges. The coring at every station indicated that oily or tarry sludges appear to have penetrated the native sands, leaving them heavily stained.

The acoustic measurements (see the contours in Figure 4-14) made in April 1983 suggest that the main pit might contain 200,000 cubic feet of sludge material. Coring in November 1983 indicates this is a lower limit to the sludge volumes in the pit. The cores where sludge thicknesses exceeded the acoustic observations were in the central and western portions of the pit. Based upon these limited measurements, the volume of sludges could easily approach 300,000 cubic feet.

These numbers provide only a general indication of the sludge amounts in the pit, because acoustic measurements are limited by the physical differences between the sludges and the underlying sands. Since sands and sludges may have become intermixed over the years by slumping or other processes, acoustic measurements may not clearly distinguish all of the sludge deposits. Similarly, coring provided a visual means of distinguishing between the sludges and the

underlying native sands. However, coring yielded information limited to only those ten sites. Volume calculations based upon only those ten sites are general estimates at best.

Since almost every coring station indicated 1 to 4 feet (see Table 4-14) of heavily contaminated sands beneath the sludges, there could be substantial quantities of this material beneath the sludges. Given the area of the main est pit, there could be 500,000 to 1,000,000 cubic feet of oil- and tar-contaminated sands beneath the sludges in the pit.

Three cores were collected with the vibracore from the lake south of Gulf Pump Road. These cores (COll through COl3) are described in Table 4-15. The locations of these cores are shown in Figure 4-15. The black gelatinous liquid layer exhibited an organic chemical odor at the time of coring. Sediment samples SOO6 and SE22 were collected from this lake for chemical analysis, with these results being presented in Section 4.6.2.

4.5 SURFACE WATER/PIT WASTEWATER SAMPLING

4.5.1 Surface Water/Pit Wastewater Site Selection and Sampling Methodology Pit Wastewater

Four surface water and six wastewater samples were collected for analysis from sites identified in Table 4-16. In April 1983, samples SW01 and SW02 were collected from the waste pit at levels 1 to 1.5 meters above the pit bottom. SW01 and SW02 represent composites of samples collected along lines that transverse the waste pit (Figure 4-16). Four aliquots were obtained from distinct points along the transverse line and then composited. Each aliquot was obtained by lowering Teflon tubing to the desired depth and sampling with a peristaltic pump operating on low speeds.

In addition to the preceding lagoon wastewater samples, a survey was done in April 1983 to determine water stratification in the waste pit. Conductivity, dissolved oxygen, pH and temperature were measured at two linear transects (north-south) corresponding with SWO1 and SWO2. Parameters were measured at four points along each transect. Results from the water stratification survey indicate dissolved oxygen stratification but no pH, conductivity, or temperature stratification (Table 4-17). The dissolved oxygen chemocline

occurred at 10 to 12 feet. Vertical profiles consisted of surface, mid-depth and bottom measurements at these points. A single vertical profile was taken at the center of the main pit (SWMAPT) at 1.5-foot intervals.

In November 1983, three more pit wastewater samples (SW07, SW08 and SW09) were collected from the same location in the center of the main pit. These samples were collected with a peristaltic pump and Teflon tubing lowered to depths of 2-, 9-, and 17-feet below the pit surface.

Surface Water

In addition to wastewater samples taken from the French Limited pit, four surface water samples were taken from area ponds and drainageways. Sample SW03 was a grab sample taken from the abandoned sand pit immediately east of the main waste pit. Sample SW04 was a grab sample taken in the pond (abandoned sand pit) south of Gulf Pump Road. Sample SW05 was a grab sample taken from the swampy drainageway north of U.S. Highway 90. Sample SW06 was a grab sample taken in the "fishing hole" beneath the U.S. Highway 90 bridge.

4.5.2 Chemical Results--Surface Water and Pit Wastewater

The conventional analyses (primarily indicator parameters) of surface waters from the French Limited site vicinity are shown in Table 4-18. The analyses for metals, PCBs, pesticides, and GC/MS fractions are summarized in Table 4-19.

Pit wastewater samples SW01 and SW02 were taken from the main pit, and both exhibited traces of phenols (see Table 4-18). All three wastewater samples from the main pit (SW01, SW02 and SWMAPT) exhibited elevated TOC levels (62,000 to 62,700 ppb). The three wastewater samples collected in November 1983 (SW07 through SW09) generally showed increasing contamination at greater depths. The sample taken from a 2-foot depth (SW07) contained 19,100 ppb TOC and 110 ppb TOX. SW08, taken 9-feet deep, showed 28,700 ppb TOC, 77 ppb TOX, and showed two base/neutral fraction chemicals above detection limits [bis(2-ethylhexy1)phthalate at 3 ppb and di-N-butyl-phthalate at 2 ppb]. The deepest sample, taken from 17 feet (SW09), exhibited a bluish tint at the time of collection, and showed 534,000 ppb TOC and 160 ppb TOX. This sample was free of pesticides and GC/MS acid fraction pollutants, but contained numerous

mg/kg = ppm.</pre>

GC/MS volatile and base/neutral fraction pollutants (see Table 4-19). Benzene was found at 1,500 ppb or more than 200 times above the human health criterion in SW09.

Other volatile organic compounds found in SW09 were: chloroform (390 ppb); 1,2-dichloroethane (190 ppb); 1,1-dichloroethylene (13 ppb); tetrachloroethene (63 ppb); trichloroethene (110 ppb); and vinyl chloride (180 ppb). SW09 contained high part per billion levels of several polynuclear aromatic hydrocarbons (detected by the base/neutral fraction), including: anthracene at 220 ppb, benzo(A)anthracene at 280 ppb, fluoranthene at 630 ppb, chrysene at 170 ppb, fluorene at 570 ppb, phenanthrene at 1,300 ppb, and pyrene at 740 ppb. The total of these polynuclear aromatics (PNA's) is about 3.3 ppm, which is over 100,000 times above the 10-5 incremental cancer risk criterion of 0.028 ppb for PNA's. In shallower waters, chloroform was detected in sample SW01 at a level of 3.0 ppb, which exceeds the human health criteria of 1.9 ppb. Other volatiles found in SW01 include: benzene (2.0 ppb), 1,1- and 1,2-dichloroethane (2.0 and 4.0 ppb) and vinyl chloride (2.0 ppb). The GC/MS acid and base/neutral fractions were less than the detection limit in SW01,

Table 4-18 indicates a change in pH and conductivity values from the April to November sampling. The overall reductions of these parameters reflect the effects the May 1983 flood had on the lagoons waters. The large dilution of lagoon waste waters by surface water during the flood can account for variance seen between the two sampling periods. (Note: November pH readings were taken using pH paper, all others with a pH electrode.)

In the surface waters north of the main pit, the analysis of SW05 showed TOC (35,700 ppb) that was triple that of SW03 from the abandoned sand pit east of the main pit (12,300 ppb) and SW06 from the "fishing hole" beneath the U.S. Highway 90 bridge (12,200 ppb). The GC/MS analysis for volatiles in SW06 was observed to be less than the detection limit, however, metals analysis indicated the presence of chromium (11 ppb), copper (6.6 ppb), mercury (0.3 ppb) and zinc (17.9 ppb).

Surface water sample SW04 taken in the abandoned sand pit south of the site showed a TOC of 12,200 ppb, no detectable TOX, and nothing in the GC/MS volatile, acid and base/neutral fractions above the the detection limit.

Like SW06, surface water sample SW04 indicated the presence of chromium (10 ppb), copper (5.6 ppb), mercury (0.3 ppb), and zinc (16.8 ppb). These metals, particularly the chromium and zinc are present in SW04 and SW06 in similar proportions as those seen in the main pit sludges.

The surface water sample SW04 from the lake south of the main pit exhibited traces of the pesticide Lindane (0.045 ppb), but was free of volatile organic compounds. The pesticide is not at a significant level (the 10⁻⁵ incremental cancer risk criterion is 0.186 ppb) and may be due to sources external to the French Limited site.

4.5.3 Pit Wastewater and Surface Water Assessment

Water contamination in the main pit appears to be quite low over the shallower depths (i.e. less than 15 feet). However, seasonal changes appear to significantly affect the concentrations of volatile organic contaminants in the upper water layers. Surface water sample SWO1 taken in April indicated the presence of trace concentrations of five volatile organic contaminants, while sample SW08 taken in November indicated no volatile organics. This observation could be attributed to the net temperature differences between April and November (approximately 20°F). The cooler November temperatures reduce the solubility of most organic compounds in water, reduce the partition coefficient between sediments and water, and reduces the rate of volatilization from sediments/sludges into the air, Wastewater sampled in November along the bottom of the pit was highly contaminated with volatile organic and base neutral compounds. Sample SWO9 appeared to have a much higher suspended solids concentration than SWOI (based on a visual comparison). The presence of high concentration of base neutral compounds in SW09 and not SW01 could be due to the high suspended solids concentration in SWO9. Also the upper water layers of the waste pit generally have a lower suspended solids concentration than the lower layers due to the gravitational settling of the solids. Therefore, the concentration of contaminants in the waters of the main pit is clearly affected by the concentration levels inthe sludges and sediments, the ambient

temperations of the sediment/water/air interface, and any disturbance which might interrupt the sedimentation process in the pit.

The waters outside the main pit do not appear to be contaminated with orgainc contaminants. This can be attributed to the lack of surface pathways connecting the different bodies of water. Runoff during non-flood periods is virtually non-existent. Evaporation and infiltration into the ground water appear to be the two dominant pathways for outflow from the main pit and other pits, marshes and sloughs in the site. The presence of metals contamination in the "fishing hole" adjacent to the main waste pit appears to be an indication of the proposed pathway. Gue Figure to

4.6 SEDIMENT SAMPLING

location 4.6.1 Sediment Sampling Site Selection and Sampling Methodology Eleven sediment samples (SEOI through SEIO) were collected in April 1983, and nineteen more (SE11 through SE29) were taken in November 1983, using either a Ponar sampler, post-hole digger, shovel or vibracorer depending on depth of water and sediment conditions. A summary of these sampling sites is presented in Table 4-20. Sampling tools were thoroughly cleaned and rinsed between sampling locations by first rinsing with water and subsequently rinsing with hexane followed by acetone. After the acetone rinse, the tool was rinsed with distilled water and allowed to dry. The first grab at each location was discarded as a further cleaning step. Lexan or PVC pipe used with the vibracore sampler was discarded after each sample was obtained. Depth of sediments sampled was 2 to 6 inches (0.05 to 0.2 meters). Sediments were composited from three to four subsamples at each location. At ponds or defined drainageways, subsamples were collected across a transect as shown in Figure 4-17.

4.6.2 Chemical Results--Sediments

4-18

Selected sediment samples were analyzed for metals. These results are presented in Table 4-21. Samples from the main pit (SEO1 and SEO3) contained elevated levels of almost all metals relative to sites outside the pit. One sample from the slough north of the pit (SEO6) was analyzed for metals and showed nothing significant. The sample taken in the abandoned sand pit east of the main waste pit (SE04) did not show significant levels of metals. The ditch

OL = less than detection limit (see Appendix J).

mg/kg = ppm.

south of the main pit (SE10) was also free of unusual metals contamination. The location of all sediment sites is shown in Figures 4-17 and 4-18.

The highest levels of organic contamination in sediment samples occurred in the main pit (see Table 4-22). Samples SEO1, SEO2, and SEO3 reflect the composition of the top 4 to 6 inches of sediment layers in April 1983. Samples SE25 and SE26 were composited over depth in November 1983 from vibracore samples (CO09 and CO10) and thus reflect a vertical average composition in the center of the pit. High levels of GC/MS base/neutral fraction compounds were seen in both April and November in all the samples, SEO1, SEO2, SEO3, SE25 and SE26. Naphthalene (8,700 ppm in SE25) and phenanthrene (8,300 ppm) were the highest concentrations observed in the base/neutral fraction. Sediments SE25 and SE26 were analyzed for the GC/MS volatile fraction, and showed benzene at 1,100 ppm in SE25 and high ppm levels of over a dozen other compounds. Total extractable organics (TOE) in the main pit sediments ranged from 7,880 ppm to 92,600 ppm. Phenols, TOX, and TOC were also high in these samples. SEO3 contained PCBs at 507 ppm, but the other samples were less than 100 ppm.

Sediment sample SE25 was further analyzed to determine the GC/MS volatile fraction content in the "head space" air over the solid portion of the sample. For this procedure, a small portion of the sediment (in this case 3.29 grams) was transferred and then sealed into a standard 40 ml VOA bottle. A small volume of gas from the head space (5 ml) was later injected into the GC column for analysis. The gas content is shown in Table 4-23. The head space analysis detected everything found in the solid sample, plus low levels of five other volatile compounds: chloroethane (4 ppm); methylene chloride (1 ppm); 1,1-dichloroethene (3 ppm); 1,1,1-trichloroethane (0.7 ppm) and 1,2-dichloropropane (0.4 ppm). For the ten volatile compounds found in both samples, the levels in the head space analysis correlated well with levels in the solid matrix.

The slough north of the main pit also contained significant yet lower levels of the same organic contamination found in the main pit sludge/sediments (see Table 4-22). TOE in SEO5 was 91,400 ppm, while TOE in all the other samples taken in the slough ranged from 209 ppm to 14,700 ppm. TOC concentrations ranged from a high of 49,100 ppm (SEI1) to a low of 2,730 ppm (SEI4). PCBs

Methodology: 3.29 grams of Sample No. 299315 were transferred into a clean VOA bottle. 5 ml of head space from this bottle was injected onto the GC column.

Notes:

- * Compounds not detected in the solid sample analysis
- † Concentration (ppm) = $\frac{(ug/m^3) (24,5000)}{(molecular weight)(10^6)}$

(1016 and 1260) were found in samples SEll through SEl4 in concentrations ranging from a high of 24 ppm (SEl2) to a low of 0.12 ppm (SEl3).

The slough north of U.S. Highway 90 was sampled (See Table 4-24). Traces of phthalates and other base/neutral compounds seen in the main pit sediments/sludges were found in this slough at fractional ppm levels and below. TOE ranged from 574 ppm (SE08) to 2,660 ppm (SE15). No GC/MS volatile compounds were found. Traces of PCBs below 1 ppm were found in samples SE16, SE17, SE18 and SE19.

Sample SE20 north of the slough area showed anthracene (0.065 ppm), chrysene (.15 ppm) and traces of six other base/neutral extractable organic compounds found in the main pit. These two compounds were not found in the slough north of U.S. Highway 90, which might reflect contaminant transport processes which are active only during high water periods (i.e. flooding).

The pit east of the main pit (SEO4) contained elevated TOE (541 ppm), but otherwise is practically free of organic contamination (see Table 4-24).

Organic analyses of other sediments collected from sites south and west of the main pit are presented in Table 4-25. Sample SE10 from the ditch immediately south of the main pit contained phenanthrene at 2.1 ppm and several other base/neutral compounds below 1 ppm that were also found in the main pit.

Sediments from the abandoned sand pit south of Gulf Pump Road (S006 and SE22) were free of volatile compounds and otherwise contained low ppm levels of phthalates and three base/neutral compounds (naphthalene, fluoranthene, and pyrene). Sample SE23 from the drainageway toward Rickett Lake also contained low ppm levels of phthalates, 16 ppm methylene chloride, and 0.008 pppm of PCB-1260. SE24 further downstream exhibited higher levels of PCBs and TOX. Sediments from Rickett Lake (SE29--see Figure 4-19) contained 0.007 ppm PCB-1260, 2.8 ppm TOX, and low levels of phthalates.

The two ponds near the Riverdale Subdivision (SE27 and SE28) exhibited 2.5 and 7.3 ppm TOK, 341 and 1130 ppm TOE, and 0.46 and 0.021 ppm PCB-1260, respectively. Bis(2-ethylhexyl)phthalate was also found in both ponds.

mg/kg = ppm.

A sample of sediments from the main pit was tested for a variety of physical and chemical parameters which could affect the selection of treatment alternatives. These test results are listed in Table 4-26.

4.6.3 Sediments Assessment

The sludges and sediments in the main pit (SEO1, SEO2 and SEO3) are substantially contaminated with naphthalene (up to 0.24 percent), phenanthrene (up to 0.18 percent), PCBs (up to 507 (pb), nitrobenzene (up to 680 ppm), and other organic compounds, Sampling by the USEPA on September 20, 1978 revealed Veri PCBs (283 ppm) and oil and grease (10.8 percent) inside the main pit. sampling in the north slough showed 1,560 ppm PCBs and 24.8 percent oil and grease. The solubility of many of these compounds is low, and consequently the surface and ground waters do not exhibit significant levels of these compounds. The volatile component of these sludges is also substantial, since benzene was found at 1100 ppm and over a dozen other compounds were seen in the high ppm range. The volatile compounds are affecting the shallow ground waters south of the main pit (see wells GW08 and GW09) at substantial (part per million) levels for some compounds. Seepage of leachate from the main pit to the shallow aquifer is occurring and appears to be transporting many of the volatile organics and some base/neutrals from the pit sludges into the shallow ground water.

The sub-bottom profiling and vibracore sampling (see Section 4.4.2) indicated sludge deposits up to 5.5 feet thick on the bottom of the central portion of the main pit. Samples SE03 and SE25/SE26 were taken closest to this zone, and showed generally the highest chemical contamination. The other samples were further from this sludge zone, and showed slightly lower concentrations. This concentration is likely to prevail across the entire underwater portion of the main pit. The vibracore samples indicate that dispersive forces (leaching, floods, etc.) over the past years have contaminated what was originally clean sands on the sides and floor of the pit. The entire bottom of the main pit is likely to be substantially contaminated to depths ranging from 1 foot up to a minimum of 6 feet beneath the sediment water interface.

Sludge/sediment deposits exhibiting substantial chemical contamination in the slough between U.S. Highway 90 and the main pit were found to depths of

12 inches in an earlier USEPA study (Nadeau, 1981). EPA's study found a distinct correlation between TOE and PCBs in sediments and cores taken from the slough area.

Sediments in the east pit (SE04) and north of the main pit (SE05, SE06, SE07, SE08, SE11, SE12, SE13, SE14, SE15, etc) exhibit definite contamination as indicated by TCK, TCC, and GC/MS base/neutral analysis, although at levels 1 to 2 orders of magnitude lower than the main pit. The Flood of 1979 created a breach in the north dike adjacent to the U.S. Highway 90 bridge, which allowed sludges and floating oily residues to escape into the backwater area beneath the bridge and between the highway and the main pit. Sediment SE20 indicates that some contaminant transport has apparently occurred into the area north of the highway, but that the contamination is not present in significant levels.

Sediments along the drainage pathway south of the site exhibit low level contamination (primarily phthalates and trace levels of PCBs) as far down as Rickett Lake. Transport of contaminants during flood events is probably the mechanism through which this occurs. Low level phthalate and PCB contamination (generally less than 1 ppm) on two ponds in the Riverdale area could also be explained by transport during flood events.

Because the major portion of the surface contamination other than the main waste pit sludges has cleaned up, the transport of contaminants by floodwaters or surface drainage is probably minimal. The contamination seen in and along the area drainageways is probably a result of past events and not an indicator of on-going surface migration of contaminants.

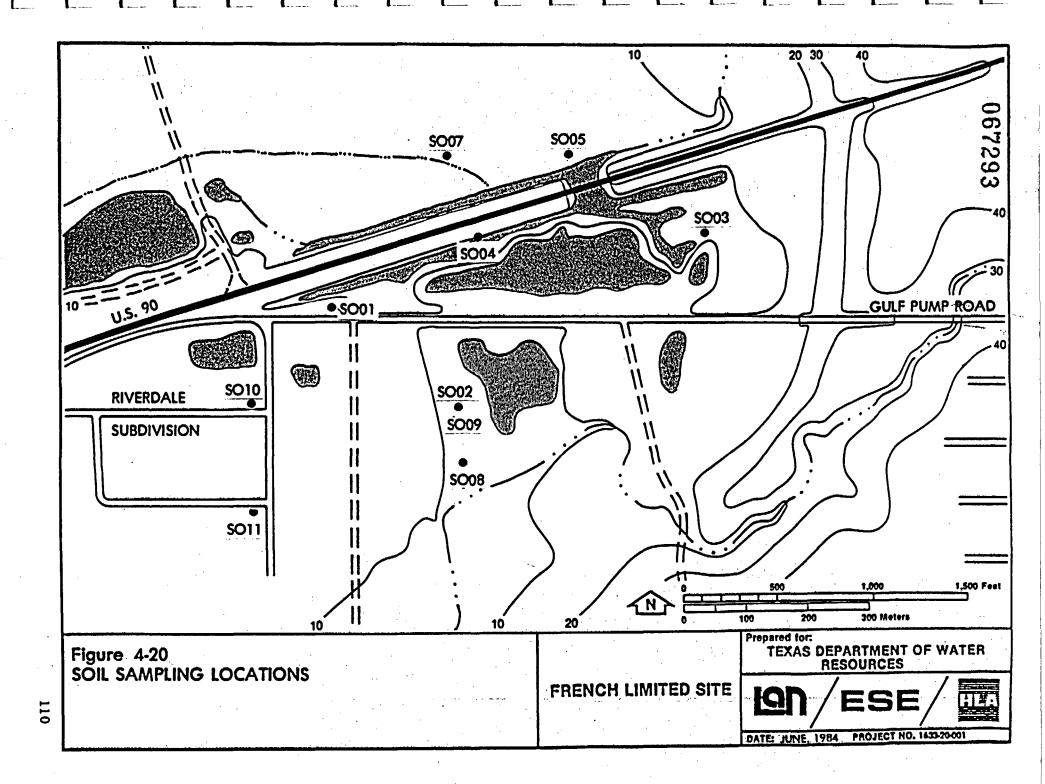

4.7 SOIL SAMPLES

4.7.1 Site Selection Sampling Methodology

Five soil samples (S001 through S005) were collected in April 1983, while five more soil samples (S007 through S011) were taken in November 1983 to supplement the previous sampling (see Table 4-27 and Figure 4-20). Soil samples were collected by compositing three to four subsamples from a given area. A hand trowel, shovel or post-hole digger was used to obtain the subsamples. The depth of the samples was 2 to 6 inches. Sampling tools were thoroughly cleaned and rinsed between each location. Cleaning involved removal of cross

Site Number	Rationale
April 1983 Sampli	ng
S001	Composite samples of soils from west end of French Limited site, near slough south of U.S. Highway 90.
S 0 2	Composite samples of soils south of Gulf Pump Road in south swampy drainageway west of Old Harris County Landfill.
s 0 3	Composite samples of soils along east site boundary.
S004	Sludge and soils above slough waterline south of U.S. Highway 90.
soo5	Composite samples of soils north of U.S. Highway 90 in marshy area flooded by past high waters.
Soc San November 1983 San	pling
S00 7	Composite samples of soils above swamp waterline north of U.S. Highway 90 between slough and swampy drainageway
S008	Composite sample of soils above swamp waterline south of Gulf Pump Road along south side of drainageway.
s ∞ 9	Composite sample of soils in swampy drainageway south of Gulf Pump Road east of the Old Harris County Landfill, same locations as SOO2.
S010	Composite sample of soils taken from dry drainage ditch in northern portion of Riverdale Subdivision.
S011	Composite sample of soils taken in dry drainage ditch in south portion of Riverdale Subdivision.

contamination followed by a water rinse, followed in turn by a hexane then acetone rinse. The sample tool was then rinsed with distilled water and allowed to air dry. The first subsample was discarded as a further cleaning step.

4.7.2 Chemical Results

Chemical analyses are presented in Table 4-28. The sludge samples SOO1 and SOO4 in the backwater area around the slough south of U.S. Highway 90 exhibited the highest levels of TOE, TOX and TOC. A high level of contamination in SOO1 and SOO4 was expected, because the major portion of these samples was dried or semi-dried sludge residue. Contaminants in SOO1 were the most concentrated, with levels of TOE at 337,000 ppm (33.7 percent), TOX at 330 ppm, and TOC at 45 g/kg (4.5 percent). SOO1 and SOO4 contained PCBs at levels of 209 and 237 ppm, respectively. SOO1 and SOO4 also exhibited significant levels of GC/MS base/neutrals, some of which were naphthalene (480 ppm for SOO4), and phenanthrene (360 ppm for SOO4). SOO4 contained levels of acenaphthene, anthracene, chrysene and fluorene which were less than the detection limit in SOO1.

The soil sample SOO5, taken in April 1983 north of U.S. Highway 90, exhibited the lowest TOX (17.2 ppm) and the lowest TOE (421 ppm) of all the soil samples. SOO5 and SOO3 (taken east of the main pit) contained 0.10 ppm and 0.22 ppm di-N-octyl-phthalate, respectively. Sample SOO7, taken north of U.S. Highway 90 in November 1983, contained 0.014 ppm PCB-1260, 2.2 ppm bis(2-ethylhexyl) phthalate, and 5.6 ppm di-N-octyl-phthalate.

Sample SOO2 taken south of Gulf Pump Road in April 1983 was observed to have TOX of 140 ppm and TOE of 1,230 ppm, which was double that of sample SOO3.

Sample SOO9 taken from the same vicinity in November had a TOX of 2.7 ppm and a TOE of 602 ppm. While sample SOO2 was not analyzed for GC/MS base/neutrals, SOO9 showed bis(2-ethylhexyl)phthalate (25 ppm) and di-N-octyl-phthalate (18 ppm) in the base/neutral fraction.

Sample S008 was collected further south of S009, and exhibited 0.15 ppm PCB-1260, 18.3 ppm TOC, 2.3 ppm TOX, and 1,630 ppm TOE.

NA = not analysed.

Obt = less than detection limit (see Appendix K).

mg/kg = ppm.

Samples SO10 and SO11, collected from the Riverdale subdivision, contained traces of PCB-1260 (0.008 ppm and 0.017 ppm, respectively). SO10 also contained a trace of PCB-1016 (0.003 ppm). Sample SO11 contained 11.5 ppm TOC and 13,100 ppm TOE, which may be due to waste oil from trucks or automobiles.

4.7.3 Assessment

Soil samples SOOl and SOO4 exhibited the highest TOX levels of any of the area samples (330 and 256 ppm, respectively). These samples (primarily dried sludge) are from the zone of heavy sludge deposits reported earlier between U.S. Highway 90 and the main pit (Nadeau, 1981). These same two samples also exhibited the highest levels of GC/MS base/neutral compounds, as well as being the samples exhibiting the highest levels of PCBs (209 and 237 ppm, respectively). PCBs may not be uniformly distributed in the slough since the sediment samples (SEO5, SEO6 and SEO7) from the same area did not show any PCBs, however, if PCBs were primarily associated with floating sludges, they would be present only to a minor extent in the slough sediments.

TOX levels in the November 1983 soil samples are much lower than levels found in April 1983. TOC and TOE were also somewhat lower in November but not significantly lower. Samples SEO2 (taken in April) and SEO9 (November) had TOX levels of 140 ppm and 2.7 ppm, respectively, and both samples were collected within 100 feet of each other from the swampy area south of Gulf Pump Road. No explanation for this difference can be found in the sampling technique or lab analytical method.

Recent flood events have transported sludge residues out of the French Limited main pit. Inspection of the area after the May 1983 flood revealed small sludge residues deposited on tree leaves and limbs south of Gulf Pump Road. The analysis of soil samples SOO7 through SOll indicates that soils away from the main pit do not appear to have been widely contaminated by past flood events.

Soil sample SOO2 was taken in April 1983 in the marshy area south of the main pit, some 400 feet along the flood pathway downstream from the main pit. The levels of TOK (140 ppm) and TOE (1,230 ppm) strongly suggest that past flood events (1969, 1973, and 1979) have indeed carried oily deposits southward

across the site boundaries. No GC/MS analysis was run on this sample. Sample S009 was taken near S002 in November 1983, and analyzed for all GC/MS fractions. S009 was free of contamination except for bis(2-ethylhexyl) phthalate (25 ppm) and di-N-octylphthalate (18 ppm). S009 was not analyzed for PCBs, but S008 further south contained 0.15 ppm of PCB-1260. One isolated finding of PCBs at this level of contamination is not sufficient to demonstrate wide-spread pollution downstream.

Bookly one avalyses

Soil sample S003 exhibited 60 ppm TOX, 646 ppm TOC, and 0.22 ppm di-N-octyl-phthalate. Since this sample, taken from the low lying area northeast of the main pit, did not show other organic contaminants found in the main pit sludges, this contamination may not be due to the French Limited site.

Soil sample SOO5, taken north of the U.S. Highway 90 bridge near the "fishing hole" beneath the bridge contained the lowest levels of TOX (17.2 ppm) and TOE (421 ppm) of any of the soil sites sampled. Di-N-octylphthalate was also seen at this site at 0.10 ppm. Contaminant transport northward from the main pit through U.S. Highway 90 bridge may have occurred. However, the absence of other contaminants in this sample raises doubt that this contamination originated from the French Limited site.

Soil sample S007 farther west from S005, indicates the same type of contamination as S005, primarily low ppm levels of two phthalates. S007 did, however, have a trace concentration of PCBs. This could have originated at either the French Limited or Sikes Disposal Pits site, existing evidence is insufficient for a conclusion.

The soils sampling and analysis suggests that significant levels of contaminants are not being transported off-site by flooding or other mechanisms. Contamination levels in the area soils indicate that some transport of contaminants may have occurred at some past time, but these transport mechanisms do not appear to be active now.

& Contradicting P3rd under Assessment

4.8 FISH TISSUE

4.8.1 <u>Sample Site Selection Rationale</u>

Five composite samples of fish tissue were taken from the fishing hole (BIO1, BIO2, BIO3, FTO4, FTO5) beneath the U.S. Highway 90 bridge and analyzed to determine if metals and PCBs were accumulating in aquatic organisms. In addition, two samples were taken from the lake south of Gulf Pump Road (FTO6, FTO7), and two samples were taken from the lake in the Riverdale Subdivision (FTO8, FTO9) (see Table 4-29). Three samples were collected using electrofishing equipment in April 1983, and six more samples were taken in November 1983. The locations of these sites are shown in Figure 4-21. Individual fish tissue samples were composites of a minimum of two specimens of a single species.

4.8.2 Chemical Results

The fish samples BIO1, BIO2 and BIO3 collected in April 1983 all exhibited mercury concentrations ranging from 0.08 to 0.17 ppm (see Table 4-30). Mercury levels were below detection limit in all samples taken in November, 1983. The tissue samples also contained polychlorinated biphenyls (PCB) levels ranging from 2 to 390 ppb. These tissues would be those fish portions consumed by humans and thus would represent a direct component in the human diet. The Food and Drug Administration (FDA) currently has a limit of 5,000 ppb for PCBs and 500 ppb for mercury in fish tissues consumed by man. The FDA limit for PCBs will be reduced to 2,000 ppb in late 1984, but this change does not affect the conclusions in this report.

4.8.3 Assessment

The levels of PCBs and mercury in fish near the French Limited site clearly do not exceed the FDA criteria for human health protection. Since the levels of PCBs observed in the second set of field samples are all less than 390 ppb.

PCBs in fish tissue do not appear to present a significant threat to human health at this time.

4.9 TERRESTRIAL ECOLOGY

The French Limited site consists of a fenced lagoon with steeply cut banks. North and northeast of the lagoon, separated by only 5 to 10 feet in some spots, are borrow pits which are filled with water. These borrow pits have been invaded by vegetation, and the vegetation in these sites could be compared with plants growing on and in the contaminated lagoon.

ug/kg = ppb.

prevense deckese

Willow, red maple, green ash, and emergent herbaceous plants exist on the edge of the borrow pits. Duckweed and algae cover the surface of the water, and frogs and turtles are abundant. Turtles and snakes were observed in the main pit and along its banks. The dominant plant on the banks was sesban, a leguminous shrub common to disturbed wet areas of Harris County. The plants on the banks showed a high incidence of dead branches, although sesban growing in nearby disturbed areas away from the lagoon were healthy and fully leafed out. In some areas of the lagoon, cattails and sedges grew in the shallow water, however, leaf death on these plants was high and they were in poor health.

If the water were to remain within the banks of the lagoon its impact on the terrestrial system would not be significant because the area of habitat loss is small. However, there is potential for flood waters to overflow the site into the nearby borrow pits and across the adjacent lands, which are used extensively by wildlife. River flooding can also carry contaminants from the lagoon to other areas where they may be toxic to wildlife and humans who consume the wildlife.

4.10 SAFETY

A site safety plan was developed to provide for protection of personnel and the neighboring environment. The Site Safety Officer was charged with implementation of the Safety Plan.

4.10.1 Well Drilling Operations

Soil boring and well drilling was an important phase in the site investigation. The work had inherent risks associated with the possibility of encountering high concentrations of gases or vapors. Drilling personnel participated in extensive physical examination prior to initiating work and wore protective clothing consisting of disposable coveralls, neoprene boots, reinforced cotton gloves with liquid-proof inserts, and hard hats. The safety officer was present at all borings and drillings to monitor the breathing zones of the drill creews. All breathing zone measurements were made with a HNU, Inc. Model 101 photoionization detector (PID) and were below 1 ppm. Half-face organic vapor respirators were available but conditions did not warrant their use. There were no exposure-related or physical injury problems throughout the duration of both drilling programs.

4.10.2 <u>Bathymetry</u>, <u>Sub-Bottom Profiling</u>, <u>and Open Water Sample Collection</u>

Small boats were used to collect samples from the main pit and other bodies of water at the site. Initial investigation of ambient organic concentrations in the air on the lagoon indicated a concentration of about 1 ppm. It was decided that all boat work on the lagoon would require organic vapor respirators.

Workers also wore disposable coveralls, neoprene boots, impervious gloves, and participated in physical examinations. The investigative work on the main waste pit was completed without incident.

4.10.3 Well Development and Sampling

This part of the site investigation was again accomplished by workers who had undergone physical exams. Protection of the workers from contact with the development water was paramount, and the use of coveralls, boots, and gloves was again employed. Constant air monitoring was necessary during well sampling to insure contaminant-free breathing. A few wells required the use of organic vapor respirators when ambient levels approached 1 ppm. All work was completed in a safe manner with no incidents. Environmental sampling in areas remote to the main lagoon (outside the "hot zone") was accomplished in normal work clothes with the use of impervious gloves.

4.10.4 Summary

Air monitoring during all work activities rarely produced readings in excess of 0.5 ppm. Steady concentrations of 1 ppm or more were used to trigger respirator use. Personal protective equipment chosen was judged to be adequate; available higher level protection was available but proved unnecessary. All medical problems were of minor significance and ranged from small cuts to minor heat stress. These conditions were easily handled on site by the Safety Officer and Field Team Leader. The public did not intervene in such a manner as to cause safety problems, and individuals encountered merely wanted to satisfy their curiosity about the site work. Emergency measures such as evacuation, police calls, or hospital calls were not necessary throughout the project duration. Decontamination procedures utilized water and detergent or degreaser to remove visible soiling, providing confidence that contamination was not carried offsite.

5.0 SITE ASSESSMENT

5.1 MIGRATION PATTERNS

5.1.1 Contamination Characteristics

Sludges in the main pit at the French Limited site contain substantial levels of volatile halogenated organics, volatile aromatic organics, polynuclear aromatic hydrocarbons, naphthalenes, phthalates, polychlorinated biphenyls, and phenolics. A summary of the peak concentrations of these compounds is shown in Table 5-1. The high levels of some of these compounds have undoubtedly masked other similar compounds from detection during this survey. Nevertheless, the compounds in Table 5-1 provide a strong indication as to the waste composition at the French Limited site. Samples from the environment around the site can be used to trace the movement of these compounds through surface water, ground water and other pathways.

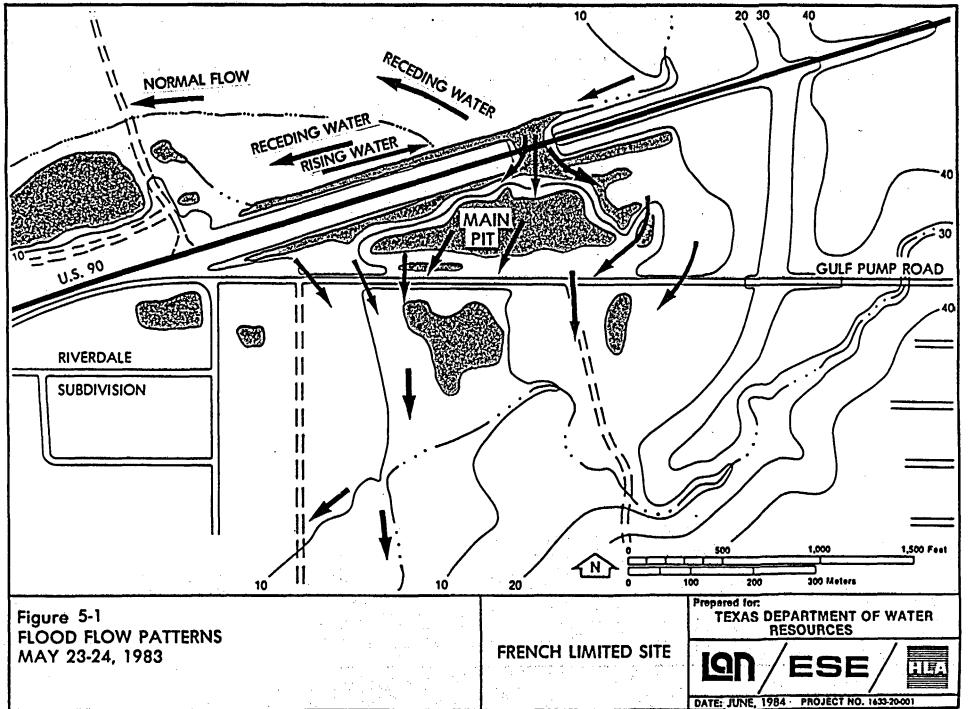

5.1.2 Surface Migration

The sludges and liquids dumped into the French Limited main pit between 1966 and 1972 have served as the chief source of environmental contamination in the site vicinity. The suspended solids in the liquids undoubtedly settled to the bottom of the pit, and the lime that French Limited added to the pit in the early 1970s to neutralize the liquids changed the surface water chemistry. The San Jacinto River floods of 1969 and 1973 exerted significant environmental forces upon the liquids and sludges in the main pit. The floodwaters diluted the liquids in the main pit and flushed substantial portions of the waterborne contaminants out of the pit. Traces of these contaminants would be found today in the downstream direction from the pit (see Figure 5-1). Sediments (at SE24 and SE29) downstream along this flood pathway show traces of PCB-1260 and elevated levels of TOE. The Rickett Lake sediment (SE29) farthest downstream showed lower concentrations than the sites closer to the main pit. Based upon observations during the flood of May 1983, the passage of these floodwaters did not appear to significantly disturb or erode the sludges in the bottom of the main pit.

The flood of April 1979 played a key role in dispersing sludges out of the main pit. This flood breached the north berm of the pit near the U.S. Highway 90

bridge which allowed sludges to move into the slough between the main pit and the highway. While EPA has since removed the floating sludges from the slough, intermittant patches of dried or partially dried sludges are evident along the banks of the slough, and the sediments in the slough still exhibit significant contamination. This contamination has also passed northward beneath the U.S. Highway 90 bridge and is now found in the slough along the north side of the road. Low levels of PCBs, naphthalene, phthalates, and polynuclear aromatics are found in the slough north of the highway. However, this contamination north of the highway is not present at significant levels, and does not pose a health hazard to the area populace.

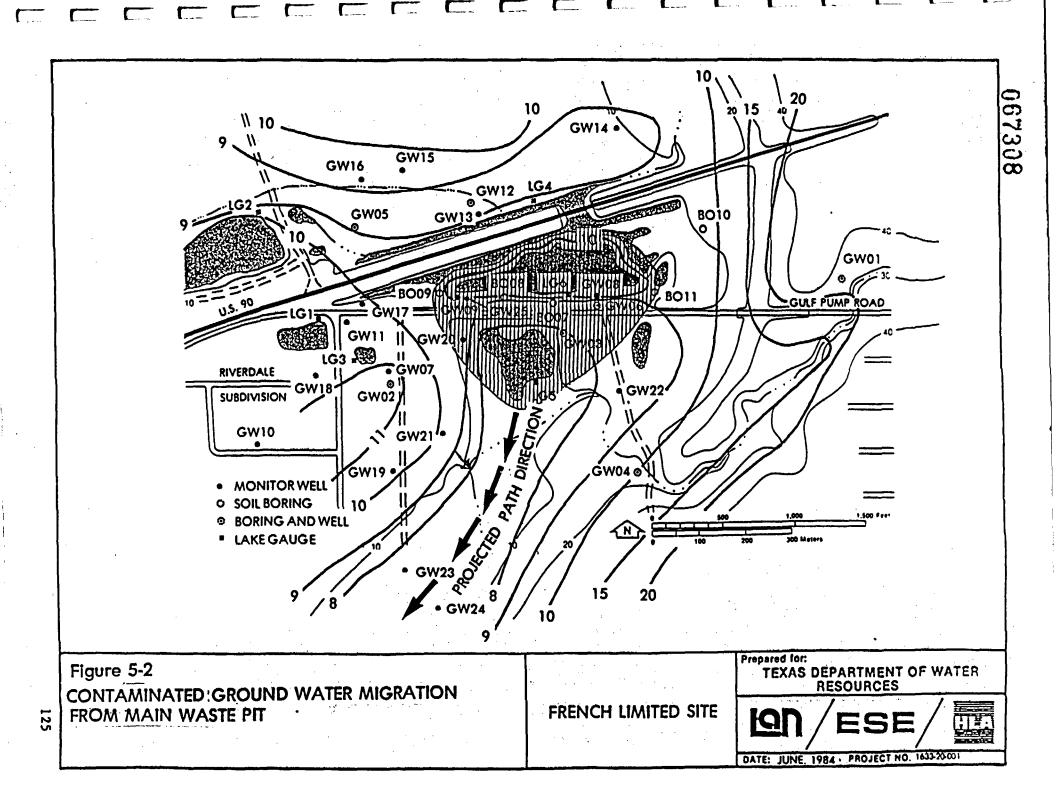

Similarly, trace levels of PCBs, polynuclear aromatics, and phthalates are found in the soils, and sediments south of the site (south of Gulf Pump Road). However, the contamination was not found at levels which might pose a health hazard to the area populace.

5.1.3 Contaminate Groundwater Migration

The existing hydraulic gradients, the calculated permeabilities in the alluvium and the result of the groundwater chemical analysis were used to determine the extent of the contaminate plume originating from the French Limited pit. The specific data used in calculating the extent of the plume is as follows:

- 1. Time span of 18 years (1966 to 1984);
- 2. Groundwater and lake elevations on December 7, 1983; and
- 3. A horizontal permeability of $3x10^{-2}$ cm/sec in the Upper Aquifer (Alluvium).

Figure 5-2 shows that the extent of the plume to the north, east and west is likely to be less than 200 feet; however, to the south the front of the plume is estimated to be approximately 700 feet from the pit and advancing about 15 feet per year. The projected path direction of the plume is also shown on Figure 5-2. As the plume extends toward the south, it will be confined to the alluvium by the Pleistocene deposits (clays) comprising the east valley wall and it will be compressed into a narrower band by the higher groundwater gradients in the Riverdale Subdivision. In approximately 100 years the front of the plume will have advanced to the southern section of the old Harris

County landfill and the marsh directly to the south. Beyond this area, there are no monitoring wells so the flow direction is not known; however, it is likely to be toward the river.

Vertical migration from the Upper to the Lower Aquifer is estimated to be approximately 0.1 feet/year. At this rate, the contaminate plume in the alluvium has penetrated the underlying Beaumont clay only a few feet and would take approximately 900 years to migrate through 90 feet of clay to the lower aquifer.

5.2 WASTE VOLUME ESTIMATES

The sludges in the main pit appear to be the principal source of contamination affecting the environment around the French Limited site. The sludges that have been dumped in the main pit have covered the deepest portions of the pit and have become mixed with the native sands, either through seepage or physical slumping of the sides of the pit. The available data suggest that there is approximately 200,000 to 300,000 cubic feet of sludges and from 500,000 to 1,000,000 cubic feet of contaminated sands in the main pit. The bathymetric study indicates that the main pit contains approximately 24.5 million gallons of water. See Table 5-2 and Section 4.4 for details.

The estimates of sludges reflect the observations in April 1983, and do not account for the total amount of sludges originally dumped into the pit (approximately 2.5 million cubic feet). Much of the waste was burned as part of the French Limited operation, also some of the floating wastes were removed and disposed of during emergency and planned removals. The San Jacinto River floods of 1969, 1973, and 1979 exerted significant environmental forces upon the sludges, and transported unknown quantities out of the pit. Some portion of the sludges was deposited nearby outside the main pit, while the remainder were carried downstream with the floodwaters.

The largest deposits of sludges outside the main pit are in the slough south of U.S. Highway 90, which contains an estimated 140,000 cubic feet of sludges and heavily contaminated sediments and soils (see Table 5-2).

Table 5-2. Waste Volumes at the French Limited Site

Medi	um	Estimated Area (acres)	Estimated Depth* (feet)	Estimated Volume
T.	Sludges/Sediments/Soils	-		(ft ³)
	Sludges in Main Pit	7.3	0.7	200,000-300,000
	Contaminated Sands in Main Pit	7.3	1.6	500,000-1,000,000
(Swamp between Pit and U.S. 90	4.6	0.7	140,000
II.	Surface Waters			(gallons)
	Main Pit	7.3	10.6	24,500,000
	Swamp between Pit and U.S. 90	4.6	2	3,200,000

^{*} Average depth over entire area.

5.3 TARGET RECEPTORS

The French Limited hazardous waste site may pose potential risks to the following types of target receptors:

- Sensitive ecosystems,
- · Natural resources, and
- Population at risk.

5.3.1 Sensitive Ecosystems

As presented in the discussion on Environmental Setting and Terrestrial Ecology, Sections 1.3 and 4.8, respectively, the vegetation, land animals, fowl and fish life in and around the French Limited site are common to the area. No sensitive habitats or protected or endangered species were observed during the site survey or are known to exist in this area.

Potential impacts on the area's ecosystem may occur via terrestrial plant uptake and plant ingestion, via surface water contamination, groundwater contamination and airborne contaminants. As noted in Section 4.8, some effects on vegetation were observed surrounding the lagoon. However, all other areas on-site and off-site appeared to sustain a healthy vegetative cover. These observations indicate that effects on the vegetative community are limited only to direct contact with the contaminants in the main waste pit and where surface water movement due to flooding has transported the contaminants along area drainageways and floodplains.

Surface mechanisms such as deposition of airborne contaminants or contact with any airborne vapors have had little if any impact on the health of the plant communities in the area. The presence of several types of animal tracks and observation of small fish in the shallow channel connecting the two parts of the main disposal pit tend to indicate limited direct impact on the immediate terrestrial and aquatic systems. However, since PCBs were found in fish tissue collected from various pits and lakes, at levels as high as 392 ppb, the French Limited site is potentially impacting the aquatic community.

Because of the observations made during the ecological "walk-over" survey of the site, the common nature of the flora and fauna in the area, and the primary

objectives of the work program, limited data were collected relative to fully defining the extent of the impacts on the area's ecosystem. Primary emphasis was placed on definition of the nature, extent, and direction of the contamination at the French Limited site.

5.3.2 Natural Resources

Site reconnaissance defined the natural resources of concern to consist mostly of forested areas, surface water channels, groundwater aquifers, and mineable sand.

While land use in Harris County is divided into cropland, pasture and range (40 percent), forested (15 percent), and the remainder urban, the immediate French Limited site and vicinity consists of forested, industrial, and residential areas.

The French Limited site is located within the 100-year flood plain of the San Jacinto River. Since the site started operations in 1966, four floods have occurred (1969, 1973, 1979, and 1983). These floods represent intense, short-duration events which inundate the site and exert significant natural forces to disperse surface contamination beyond the site boundaries. The floodwaters in 1979 successfully eroded the north berm of the main pit and created a pathway for sludge and sediment outflow into the adjacent swamp.

Surface waters in the vicinity of the French Limited site are used for recreational activities, primarily fishing. PCBs were found between 18 and 194 ppb in fish fillets taken from the local "fishing hole" beneath the U.S. Highway 90 bridge immediately north of the main pit and up to 392 ppb in fish from lakes south of Gulf Pump Road. Since fish from the "fishing hole" north of the main pit do not exhibit PCBs higher than from the lakes south of Gulf Pump Road, a clear link between PCB in these fish and sludges from the pit cannot be established.

Contamination of the soils in the site area could pose a hazard to human health if agricultural development of these areas were to take place in the future. Uptake of contaminants by vegetation destined for consumption by cattle or

humans could result. The commercial development of land areas potentially affected by the site appears to be highly unlikely. A large portion of the area around the site lies within the 100-year floodplain of the San Jacinto River and Harris County, and the federal government restricts building and development in flood prone areas. In addition to being in the floodplain the area is relatively far removed from the metropolitan Houston area and not readily accessible to large work centers. Improvements necessary to remedy the situation do not appear feasible at this time; however, construction of the new U.S. Highway 90 may change the development outlook and thus area land use.

There are approximately 34 residences in the Riverdale Subdivision and another seven residences along Magnolia Drive (west of Riverdale) that are within 4,000 feet of the French Limited main pit. Of these residences, 14 are known to draw water supplies from wells less than 100 feet deep (see Appendix M). These residences are listed in Table 5-3. The closest wells to the main pit are along Maple Drive (within 1,000 feet of the main pit). The source of domestic water for the other 27 houses is either deep wells (greater than 100 feet deep), unidentified shallow wells or hauled-in water. These residences are at slightly higher elevations (about 20 feet above mean sea level) than the main pit, and the water table in this area in the direction of the subdivision is slightly higher than the site vicinity. Nevertheless, ground water beneath the French Limited site appears to be moving southward (east of Riverdale) and westward (north of Riverdale). Thus, if the shallow groundwater gradients temporarily disappear or shift, these residences could be subjected to shallow groundwater contamination, either from the east or from the north. Assuming all residences are occupied, and occupancy averages three people per household, then as many as 123 people could be exposed to groundwater contamination from the French Limited site.

The high concentrations of groundwater contamination were found in shallow wells along the south side of the French Limited main pit. If the sludges in the main pit causing this contamination are left in an uncontrolled state for long periods of time (i.e. decades), shallow ground waters further removed from the French Limited site will become contaminated at levels exceeding the current human health criteria. The nature and thickness of the clay layer

^{*} Other shallow wells which have not been reported may exist in the area.

underlying the site makes contamination of the lower aquifers highly unlikely. If, however, contamination was introduced (by faulting, drilling, etc.) into the lower aquifer a significant number of people potentially could be affected. Five major drinking water wells screened as shallow as 200 feet are located within 2 miles downgradient of the French Limited site. These wells supply the town of Barrett, the City of Crosby, and other nearby communities.

No contamination criteria exist for soils and sediments. However, the high levels of sediment contamination observed in the main pit and in the slough between the main pit and U.S. Highway 90 are exposed to large natural dispersion forces (chiefly floods). Significant health risks would be created if these sludges and sediments were dispersed in an uncontrolled fashion. Soils and sediments farther removed from the French Limited site, but still in the immediate vicinity, appear not to be significantly affected by past flood events. The primary risk involved off-site is contact with undiluted heavily contaminated sludges or sediments transported intact from the site area. Previous removal actions at the site have removed the bulk of surface contamination making this highly unlikely, while off-site accumulation of sludges is minimal to non-existent.

5.3.3 Population at Risk

The French Limited site is approximately two miles southwest of Crosby, Texas and one mile west of Barrett, Texas. The combined population of the Crosby/Barrett area is approximately 5,250 based on the 1980 census. Southwest of the site is the Riverdale Subdivision with a residential population of less than one hundred people. Other homes are located along Gulf Pump Road south of the site and U.S. Highway 90.

The Crosby/Barrett area is primarily residential with some commercial businesses and some sand mining operations along the San Jacinto River and its tributaries. Some farming also occurs in the outlying areas. Approximately one-half mile west of the site, on the western bank of the San Jacinto River, St. Regis Paper Company operates a pulp/paper mill.

The French Limited site is surrounded by densely wooded lands and intermittent swampy areas. The area contains numerous abandoned sand pits which are frequented by area sport fishermen.

The population potentially at risk includes:

- residents in the nearby Riverdale Subdivision;
- · residents along Magnolia drive;
- employees of the nearby sand mining operations
- sport fishermen that frequent the San Jacinto River, and some of the abandoned sand pits;
- travelers along U.S. Highway 90 and Gulf Pump Road; and
- Harris County, Precinct 2 maintenance personnel.

In examining the population at risk, it is important to consider the mechanisms or pathways by which these people may become exposed to the contamination. The primary pathways of potential concern for the French Limited site area are:

- 1. consumption of contaminated ground water,
- 2. ingestion of contaminated aquatic species and plants,
- 3. direct contact with contaminated soils and surface water, and
- 4. inhalation of airborne contaminated dust.

Although all four of the pathways defined above have the potential for producing acute short-term effects, the first pathway (consumption of contaminated ground water) is most likely to produce serious long-term effects.

Based on the above discussion and the potential population at risk, the residents in the Riverdale subdivision and those along Magnolia Drive are most likely to suffer long-term chronic effects as well as any acute effects.

Because of the popularity of sport fishing in and around the French Limited site, and the potential for this segment of the population to be subjected to the contamination from the French Limited site by all of the last three pathways defined above, the sport fishermen are considered to be the second most likely segment of population at risk to suffer both acute and

chronic effects. However, because of the surface water removal mechanisms observed at the site, that is, the persistent flooding of the disposal area and the movement and dispersion of contaminants, the effects resulting from the last three pathways of exposure will continue to diminish. On the other hand, the potential for well water contamination will continue to increase as the contaminant plume moves outward from the immediate site area. This movement will occur as long as a sufficient concentration of the contaminant mass remains within the French Limited site. Once the source mass is removed the potential for exposure to contamination from the well water will diminish accordingly.

5.4 SIGNIFICANCE OF WASTE CONCENTRATIONS

The waste chemicals at the French Limited site are present in the sludges and sediments in the bottom of the main pit and in the soils and sediments of many of the adjacent pits and ditches. Surface waters in the main pit contain low ppb levels of the more soluble chemicals (chiefly volatile organics), while the ground waters immediately south of the main pit contain significant (high ppb) levels of these same volatile organics.

Mercury was the only inorganic chemical (observed at 0.7 ppb in ground water with a criterion of 0.144 ppb) observed in water above its 10⁻⁵ incremental cancer risk human health criterion (see Appendix F), and it appeared only in the background well. No groundwater wells on the site proper exhibited mercury contamination. Additionally, this level of mercury is below the 2 ppb primary drinking water standard.

A comparison of the highest observed concentrations in water at French Limited with the 10^{-5} risk level human health criterion is shown in Table 5-4. Both ground water and surface water concentrations are shown in the table. The 10^{-5} human health criteria were used for comparison due to the lack of drinking water standards governing most of the organic compounds found in the ground water. One compound, tetrachloroethene, was found in ground water at more than 100 times its 10^{-5} human health criterion level. Four compounds were seen in ground water at between 10 and 100 times their 10^{-5} human health criteria: benzene, carbon tetrachloride, 1,2-dichloroethane, and

Table 5-4. Summary of Maximum Concentrations at French Limited and Human Health Criteria (All Units in ug/l or ppb)

lindane	0.186	-	0.045
mercury	0.144	0.7†	-

^{*} Values correspond to the proposed 10^{-5} incremental cancer risk levels for human health protection as discussed in Appendix F.

[†] Exceeds the 10⁻⁵ human health criterion.

methylene chloride. Three compounds in ground water (trichloroethene, vinyl chloride, and mercury) and one compound in surface water (chloroform) were observed at between 1 and 10 times their 10⁻⁵ human health criteria. Several compounds attributed to the French Limited site were found below the criteria levels in both ground water and surface water.

A summary of the observed metals contamination and the Primary Drinking Water Standards (see Appendix F) is presented in Table 5-5. No metals were observed above the drinking water standards.

The high concentrations of groundwater contamination were found in shallow wells along the south side of the French Limited main pit. If the sludges in the main pit causing this contamination are left in an uncontrolled state for long periods of time (i.e. decades), shallow ground waters further removed from the French Limited site will become contaminated at levels exceeding the current human health criteria.

No contamination criteria exist for soils and sediments. However, the high levels of sediment contamination observed in the main pit and in the slough between the main pit and U.S. Highway 90 are exposed to large natural dispersion forces (chiefly floods). Significant health risks would be created if these sludges and sediments were disturbed in an uncontrolled fashion.

Water Quality Standards and Criteria

APPENDIX F

Pursuant to Section 1412 of the Public Health Service Act, as amended by the Safe Drinking Water Act (Public Law 93-523), EPA has promulgated National Interim Primary Drinking Water Regulations (NIPDWR) (EPA, 1981) and National Secondary Drinking Water Regulations (NSDWR) (EPA, 1981s). These regulations establish primary and secondary maximum contaminant levels (MCLs) for certain inorganic and organic substances in drinking water. The primary MCLs control contaminants which adversely affect health, while the secondary MCLs control contaminants that affect the aesthetic qualities relating to the acceptance of drinking water. At considerably higher concentrations of the secondary contaminants, health implications may also exist, as well as aesthetic degradation (EPA, 1981; EPA, 1981a).

EPA (1976) has developed water quality criteria for the protection of human health and aquatic life, pursuant to Section 304 of the Clean Water Act. In 1980, EPA criteria were updated for the 64 toxic pollutants or pollutant categories named in Section 307A of the Clean Water Act, based on evaluation of new toxicological and environmental data and changes in the approach to hazard/risk assessment. The 1980 criterion for mercury was additionally revised in 1981 (EPA, 1981b). The 1980 and 1981 EPA criteria superceded the 1976 criteria for the 64 toxic compounds, since these were evaluated by the more advanced methodology. The new EPA criteria considered the acute and chronic adverse effects of water pollutants on aquatic organisms, nonhuman mammals, and humans. These criteria have been designed to protect aquatic life and humans from effects of exposure to the pollutants.

The level of protection afforded aquatic organisms by the 1980 and 1981 EPA criteria is that most aquatic life would be protected and aquatic ecosystem functions would be preserved, but that a few untested species might be adversely affected if the highest allowable concentrations

persisted for long periods of time. The 1980 and 1981 EPA criteria specify both concentrations in terms of 24-hour averages and maximum concentrations not to be exceeded at any time. Since the sampling program in the environmental survey did not quantify 24-hour averages, assessment of potential effects on aquatic life has been made by comparison to EPA criteria which are the maximum allowable concentrations at any time. These criteria are shown in Table F-1 for the contaminants observed at the French Limited Site.

Human health criteria have been incorporated by EPA into the 1980 and 1981 criteria, based on the carcinogenic, toxic, or organoleptic (taste and odor) properties of the 64 toxic pollutants. For those noncarcinogens, the criteria have been based on the prevention of adverse health effects in humans. In the case of suspected or known carcinogens, the criteria represent incremental increases in the cancer risk to exposed populations. In assessing the human health significance of contaminants at French Limited, the incremental risk level chosen was 10⁻⁵. This level is the concentration of a specific contaminant, which is projected by the EPA risk analysis to potentially increase the incidence of cancer by no more than one case per 100,000 individuals. The applicable human health criteria for the contaminants found at French Limited are shown in Table F-1, both for human consumption of water and organisms and for human consumption only of organisms taken from water containing the contaminant. The EPA methodology for development of the criteria for protection of both human health and aquatic life are summarized in EPA (1980). No soil or sediment criteria have been developed.

In assessing the significance of contamination at French Limited, the criteria and MCLs have been applied as follows. For materials contaminating the bedrock aquifer, the maximum drinking water contaminant level has been considered the most critical concentration upon which the assessment is based. This is because the principal environmental/health affects would stem from use of the ground water as

a domestic water supply. Water in the bedrock aquifer may, however, discharge to the surface water, where contaminants could affect aquatic life. For materials contaminating the ground water contained in the unconsolidated sediments above bedrock and for surface waters, the most stringent of the following criteria has been considered the critical concentration upon which the assessment is based: (1) the maximum drinking water contaminant level, (2) the criterion for protection of freshwater aquatic life, or (3) the criterion for protecting human health when both aquatic organisms and water are ingested. The lowest of these three concentrations is the maximum level tolerable in the shallow ground water and surface water at French Limited since the surface waters may be used for water supply, fishing, or propagation of aquatic life.

BOOKMARK

APPENDIX G
Chemical Analysis Methods

APPENDIX G Chemical Analysis Methods

Samples were analyzed for pH, conductivity, total organic extractables (TOE), total organic carbon (TOC), total organic halides (TOX), metals, phenols, polychlorinated biphenyls (PCBs/pecticides), volatile organic acids (VOAs), base neutrals (B/N), and acid extractables (acids).

Table G-1 summarizes the analytical methods used for each parameter of interest. Table G-2 lists the analytical holding times and preservatives which were used for all ground and surface waters. Soils, sediments, sludges, and fish were kept at 4°C until analyzed. These were not required holding times for these matrices, but every effort was made to extract the smaples within seven days for organic analysis.

In situ parameters, to include pH and conductivity, were measured to give information as to the conditions of the area at the time of the sampling.

The analytical protocol was directed towards screening to identify major organic compounds and metals. The screening procedure included analyzing for TOE, TOC, TOX, metals and phenols. TOE was analyzed by freon extraction followed by infrared determination. TOC was measured by the method of combustion using the Oceanography International Model 915A TOC analyzer. Metals analyses was carried out on a Jarrel-Ash 1100 Simultaneous Inductively Coupled Argon Plasma Spectrometer (ICAP). This procedure has the capability of analyzing up to 33 metals simultaneously on a sample. For the initial phase of the survey, the 13 metals listed in Table G-3 were determined by ICAP, with data for the additional 20 metals made available for further waste characterization. Total phenols were determined spectrophotometrically by the 4-aminoantipyrine (4-AAP) method. TOX was determined by the microconlumetric-titration method using the Dohrman DX-20 TOX system. Detection limits for the above parameters in both liquid (ground water

and surface water) and solid (sediments, soils, and fish) matrices are given in Table G-3. The detection limits given in Table G-3 are values typically achieved by the methods described above. For any individual data set, the actual detection limits are a function of matrix type, chemical interferences, instrument noise, and other factors affecting the individual analytical run. The appendices in this report which present the chemical results may contain detection limits which deviate from Table G-3 because of these factors. Different detection limits arise for each individual data set depending upon the instrument readings for repetitive blanks for the lowest standards included in the run.

Selected samples were analyzed by gas chromatography (GC) and gas chromatography/mass spectroscopy (GC/MS) for qualitative and quantitative identification. PCBs/pesticides were analyzed by GC with electron capture detector. Detection limits for this method are summarized in Method 608 Organochlorine Pesticides and PCBs (Appendix A in the Work Plan). The GC/MS analysis determined the organic compounds on the priority pollutant list. VOA, B/N, and acid compounds were analyzed by GC/MS. Detection limits for these compounds are given in Federal Register, Methods 624 and 625 (Appendix A in the Work Plan).

INTEROFFICE MEMORANDUM

APR 2 3 '84

ENFURCEMENT ANL

TO : Chris Lippe, Solid Waste and Spill Response

DATE: Aprifield, OPSBATIONS

THRU

FROM : Clarence E. Johnson, Field Representative, District 7

SUBJECT: French Ltd. of Houston Pit, Crosby, Super Fund Site

I. Introduction

The French Ltd. of Houston site located in a sandpit off Hwy. 90 near Crosby originally was operated by Mr. B.G. Burton. French Ltd. of Houston, Inc. bought the site in June, 1967. It was operated by French Ltd. of Houston until May 3, 1971 when a temporary restraining order was granted by a Harris County District Court. The site was used by French Ltd. vacuum trucks only and received 70,000,000 gallons per year of industrial solid waste liquids and sludges.

The site in May, 1971, when it was shut down contained 2 - 3 feet of heavy oils on the surface (PCB contaminated); wastewater in pit had a pH of 1.9 and COD of 35,000 - 40,000 mg/l.

The 189th District Court through court orders issued every 60 days required the almost bankrupt French Ltd. of Houston, Inc. to remove and burn in their burners the heavy oils on the pit, neutralize the acid in the pit with 20,000 tons of cement plant flue dust (80 - 90% lime), and aerate the pit.

In June, 1973 a 100 year flood on the San Jacinto River covered the pit and flushed out most of the wastewater, when the dikes were breached in two spots.

The 189th District Court then required that the dike be repaired, all structures demolished, the land deeded to the State of Texas, and \$20,000 fine paid to Harris County.

II. Findings

- Sandmining occurred in the French Ltd. Pit area before the sandpit was used for industrial solid waste disposal. These sandpits usually dropped the water table in the sandpits 15 - 30 feet.
- 2. Two large sandpits started operations during the operation of the French Ltd. Pit. The water in these sandpits became contaminated within 30 60 days.

Mr. Brian Dixon Page 2 April 13, 1984

- 3. The residents of Riverdale Subdivision, southwest of the French Ltd. Pit for the most part had shallow private wells 25-75 feet deep. In the early 1970's these wells were sampled by District 7 and Harris County Pollution Control. The well water had a hydrocarbon or chemical odor, a floating film of oil (rainbow), low pH, COD contamination, and heavy metals.
- 4. Harris County Precinct 2 operated a burning garbage dump for over 20 years adjacent to Riverdale Subdivision on the east. In 1967 this was converted to a "sanitary landfill", whose trenches were 20 feet deep into the water sand. These trenches always had water in them with an oily film and chemical odor.
- 5. Good drinking water in the area required a 300 feet deep well which French Ltd. of Houston had at the site and several other nearby residents.
